The global time scale is ideally related to the center of the mass of Earth as the effect of external gravitational bodies disappears. For practical reasons timekeeping is not possible at the center of Earth's mass. Therefore the time scale definition of "Temps Atomique International" (TAI) refers to a geocentric reference system with a definition of the second related to the equipotential surface of the rotating geoid. The world time is the *Coordinated Universal Time* (UTC) which is

TAI corrected by an integer number of leap seconds realized by local clocks. The unit of the time second is realized by cesium frequency standards. Its SI definition is: The second is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium atom ^{133}Cs (BIPM 1998).

The metric scale is a secondary unit derived from the definition of the time second and the constant of the speed of light. The meter is defined as the distance traveled by light in vacuum in $1/299,792,458$ s. Depending on the definitions for speed of light and time second, the metric scale is only valid in the vicinity of the time second-defining clock. That is why large distances should be seen as space-time intervals which are characterized by two-way measurements or one-way measurements with clock transportation.

The mass of Earth could be seen as constant if there were no exchange of radiation with the ambient universe. With respect to the terrestrial reference frames, the solar system with its gravitating bodies is seen as sufficiently isolated. The universal gravitational constant, $G = 6.674,30 \cdot 10^{-11} \text{ m}^3/\text{kg}/\text{s}^2 \pm 0.000,15 \cdot 10^{-11} \text{ m}^3/\text{kg}/\text{s}^2$, is known with its relative standard uncertainty of $2.2 \cdot 10^{-5}$ (NIST Reference 2018). G is the only link between the SI unit for mass and the gravitational phenomena. Given that only in the magnitude 10^{-17} the tidal potential at the height of the geoid has an effect on the definition of the time second, the value of G may be applied in geocentric as well as in barycentric reference systems. The product of the universal gravitational constant with the mass of Earth is called the geocentric gravitational constant, $GM = 3.986,004,418 \cdot 10^{14} \text{ m}^3/\text{s}^2 \pm 8 \cdot 10^5 \text{ m}^3/\text{s}^2$, and can be determined with higher accuracy ($2 \cdot 10^{-9}$) than the individual factors (10^{-4}). It is used for geodetic Earth models.

The IERS Conventions and IERS Standards mirror the actual status of parameters and models to be used in order to obtain a consistent TRF approximating the underlying physical theories with the best available models and constants (IERS 2010).

Global Geodetic Reference Systems

With the beginning of the satellite age, the need for an accurate global geodetic reference system became evident. Also spatial and geographical information datasets extending over national boundaries are calling for a common global reference frame for collection, storage, visualization, and exchanging of geoinformation. On February 26, 2015, the General Assembly of the United Nations adopted Resolution 69/266 A global geodetic reference frame for sustainable development (UN69/266) urging member states to contribute.

Global geodetic reference systems have always been based on definitions and measurements with respect to the available scientific knowledge and technology. In former times solid Earth models had been sufficient for global reference frames,

scientific geodetic studies, and for mapping applications. Modern geodetic space techniques such as very-long-baseline interferometry (VLBI), satellite laser ranging (SLR), global navigation satellite systems (GNSS), and modern instrumentation of local sensors such as absolute gravity meter (AG) and superconducting gravity meter (SG), providing much higher resolutions in the measurements, showed the variability of the observables as a function of time. Consequently, the solid Earth models had to be replaced by viscoelastic Earth models.

For the purpose of reference frames, the viscoelastic Earth models must also include models of plate-tectonic motion because reference points at different continental plates expose different directions and velocities of proper motion over time. The exhaustion of the kinematic motion of individual reference points is achieved in the coordinate estimation under the condition that the squared sum of the individual point motion is made to zero. This condition is commonly expressed as *no-net-rotation* (NNR).

As it appears to be an impossible task to fix a static and very precise global coordinate system on the continuously changing Earth, a permanent monitoring of reference positions in geodetic networks became necessary. These permanent observing networks, in which fundamental stations for geodesy have an indispensable role, are the bases for global geodetic reference frames.

Currently two global geodetic reference systems have a major importance: ITRS and WGS84.

International Terrestrial Reference System (ITRS)

The most important conventional terrestrial reference system (CTRS) is the International Terrestrial Reference System (ITRS). The ITRS is defined as a Cartesian coordinate system in which (a) the origin coincides with the center of Earth's mass (including the masses of the hydrosphere and the atmosphere), (b) the metric scale is defined by the fixed velocity for the propagation of light in a gravitating environment and the physical definition for the unit of time according to SI, (c) the orientation is obtained by observation of Earth rotation relative to space-fixed objects of the celestial reference frame (ICRF), and (d) the system has no global residual rotation with respect to horizontal motions at the Earth's surface (NNR) (IUGG 1991). The definition of origin, scale, and orientation is the *geodetic datum* of a reference system. If a geographic coordinate system (latitude, longitude, ellipsoidal height) is chosen, the corresponding parameters of the desired reference ellipsoid must also be defined and become in general part of that datum. The GRS80 ellipsoid (Moritz 2000) is often used for the ITRS as best fitting the global figure of Earth's surface.

The database of the IERS Terrestrial Reference Frame (ITRF) is provided by International Services for VLBI,

SLR, GNSS, DORIS, and the collection of local surveys at collocation sites with multiple techniques.

The ITRF is published with respect to certain epochs, i.e., the ITRF2014 is based on observation data of more than 1,499 stations located in 975 sites, where about 10% of them are co-located with 2, 3, or 4 distinct geodetic instruments (IERS 2017). The ITRF coordinates and velocities of the reference points are estimated in the processing of observational data. Each reference frame refers to a specific epoch and shall allow linear extrapolation of the coordinates to any desired epoch. However, long-term series and certain geographical regions partly expose nonlinear evolution of point positions and require frequently updated regional reference frames or nonlinear motion models (Altamimi et al. 2016).

The updating of the ITRF is necessary not only due to the continuously acting geodynamic forces on the global network and the need to update reference points but also due to the introduction of improved models in the data reduction and new stations. For the generation of each new frame, the NNR condition is applied. The IERS Conventions contain the adopted constants, parameters, and models which shall be used for data processing (IERS 2010).

World Geodetic System 1984 (WGS84)

WGS84's geometrical base is comprised of (a) a global coordinate frame for the Earth and (b) a standard spheroidal reference surface (the *datum* or *reference ellipsoid*) for raw altitude data. In addition, the geophysical base is a gravitational equipotential surface model (the *geoid*) that defines the nominal sea level. The geophysical base was periodically updated as the underlying Earth Gravitational Model (EGM96, EGM2008) improved by its ground resolution from 200 km to 10 km.

The geometrical definition of WGS84 identifies Earth's center of mass as the origin of the coordinate system. The *zero longitude* is identified with the IERS Reference Meridian, which lies 5.31 arcsec east of the Greenwich Prime Meridian for historical reasons related to the NNSS Doppler System.

The WGS84 is defined and maintained by the US Department of Defense. The GPS control segment consists of only a few globally distributed reference stations, whose coordinates together with the broadcast ephemerides are expressed in this datum. The control segment network is also called *zero-order network* as it fixes the reference frame.

Consequently any GPS user who wants to determine a position in WGS84 is dependent on how accurately known the satellite orbits are with respect to the control segment reference stations. Due to orbit perturbations, the broadcast ephemerides are only approximations and need frequent updates. In absolute positioning mode, results are said to be in the WGS84 datum. In relative positioning model, a baseline vector between two stations can be determined with much

higher accuracy. However, the datum is almost completely defined by the base station, which has a much higher uncertainty than the baseline vector. It is therefore desirable to tie GPS baseline vectors to ITRF reference stations using the precise orbit product of the International GNSS Service (which is obtained from hundreds of network stations) and express sets of estimated coordinates related to the most recent ITRF. The *absolute accuracy* is defined by the true relationship of a position to the coordinate datum. The ITRF is multi-technique based and with a higher number of network stations, for which reason the ITRF provides a higher absolute accuracy than the WGS84 in its current configuration.

As it can be recognized by the defining parameters (Tables 1 and 2), the ITRS and WGS84 coincide within a few cm.

Continental Reference Systems

Like the surveying practice “working from the whole to the part,” continental and national reference frames are established using subsets of reference points defining the global terrestrial reference frame. These can be ordered hierarchically beginning with the global terrestrial reference frame (TRF) in which the origin, orientation, and scale are defined. The continental reference network contains the corresponding subset of the global reference points providing

Geodesy, Networks, and Reference Systems, Table 1 Defining geometrical and geophysical parameters of the Geodetic Reference System 1980 (GRS80). The dynamical flattening expressed by the dynamical form factor J_2 and determined by satellite orbit perturbations was given preference in the definition. The geometrical flattening $f = 1/298.257,222,101$ became a derived parameter (Moritz 1980)

Defining parameters of GRS80	Symbol	Value
Semimajor axis or equatorial radius	a	6,378,137.0 m
Dynamical form factor	J_2	0.001,082,63
Geocentric gravitational constant (incl. atmospheric mass)	GM	$398,600.5 \cdot 10^{+9} \text{ m}^3/\text{s}^2$
Angular velocity of Earth rotation	ω	$0.729,211,5 \cdot 10^{-4} \text{ rad/s}$

Geodesy, Networks, and Reference Systems, Table 2 Defining geometrical and geophysical parameters of the World Geodetic System 1984. As opposed to the GRS80, the geometrical flattening, f , is the defining quantity and the dynamical flattening given by the dynamical form factor $J_2 = 0.001,081,874$ which is a derived quantity

Defining parameters of WGS84	Symbol	Value
Semimajor axis or equatorial radius	a	6,378,137.0 m
Flattening $(a-c)/a$	f	$1/298.257,223,560$
Geocentric gravitational constant (incl. atmospheric mass)	GM	$398,600.441,8 \cdot 10^{+9} \text{ m}^3/\text{s}^2$
Angular velocity of Earth rotation	ω	$0.729,211,5 \cdot 10^{-4} \text{ rad/s}$

Geodesy, Networks, and Reference Systems, Fig. 1 Hierarchical relationship between different reference frames. The International Terrestrial Reference Frame (ITRF) is tied to the space-fixed International Celestial Reference Frame (ICRF) via the Earth orientation parameters (EOP). The Earth-fixed ITRF depends on the observational data from fundamental stations to define its origin, orientation, and scale. Subsequent frames on the continental, national, regional, or local level are consistent with each other if they are including reference points from the superior level (shown here is the example of Argentina in South

America). Thus the definition of the global reference frame is introduced into the continental SIRGAS and into the national POSGAR reference frame until to the level of cadastre in towns. The shape of the triangle symbolizes the increasing number of reference points. On the top level, only a few global reference points (fundamental stations) for the definition of scale, origin, and orientation are necessary. On the bottom level, the maximum number of reference points is needed for large-scale mapping and cadastre purposes

the consistent frame and is densified by additional reference points. Consistency to the global reference frame is achieved by the network adjustment with the introduction of the global definition of origin, scale, and orientation represented by the subset of global reference points. National reference frames are established by composing the network of the corresponding global and continental reference points on national territory and additional densifying of national reference points. Thus the densification of geodetic networks can be done in a consistent way to the most accurate global terrestrial reference frame, the ITRF. One example for consistency between hierarchical reference frames is the geocentric reference frame of the Americas, SIRGAS, and subsequent national reference frames in South-American countries (s. Fig. 1). The GRS80 is mostly adopted as the reference ellipsoid for the continental reference frames for consistency reasons to the ITRF (Table 3).

Continental vertical reference systems have to overcome the national height system definitions and to be made consistent at the borders. Usually in continent-wide measuring campaigns at tide gauges and at national first-order reference points with leveling, GNSS and gravimetry are performed to resolve this task. An example is the European Vertical Reference System (EVRS) in its realization of the European Vertical Reference Frame 2007 (Ihde et al. 2008).

National Geodetic Reference Systems

GNSS techniques turned the former particular national reference system into being part of a superior continental or global reference system. National geodetic networks are needed to provide a reliable common coordinate system for spatial datasets and geographical information data. At present most national geodetic network infrastructures consist of

Geodesy, Networks, and Reference Systems, Table 3 Continental reference frames

Continental reference frames	Acronym	Meaning	Earth model
Africa	AFREF	African Geodetic Reference Frame	WGS84
Asia-Pacific	APRGP	Asia and Pacific Regional Geodetic Project	GRS80
Europe	EUREF	European Reference Frame	GRS80
North and South America	SIRGAS	Geodetic System for the Americas	GRS80

continuously operating reference stations (CORS), which are linked to the ITRF. A GNSS CORS comprises a GNSS receiver with its antenna mounted on a stable monument at a safe and secure location equipped with a reliable power supply and a connection to the communication networks for data transmission. Different services make this infrastructure available to the users: (a) streaming real-time (raw) data over the Internet (NTRIP); (b) streaming real-time kinematic data (RTK) and differential GNSS data (DGNSS) for applications such as RTK survey, GIS data acquisition, and GNSS navigation; and (c) transfer of hourly or daily data files to an FTP server.

The national coverage with CORS depends on the resources available and on the tectonic situation. A good example is the Japanese GPS Earth Observation Network (GEONET) with more than 1,300 CORS. This network with 30–50 km distance between each CORS is used for land survey but also for the monitoring of seismic and volcanic activities.

For historical reasons national geodetic systems may still refer to a best-fitting ellipsoid as a reference surface to the

given national latitudes. With the introduction of the hierarchy of reference systems, the global Earth models are becoming more important especially for national reference systems due to consistency.

Vertical national reference systems are usually related to a tide gauge. The *zero height* can be related to an average level of the sea water height (i.e., mean sea level). Some countries transferred the vertical reference from the tide gauge by spirit leveling to a distant benchmark at a secure location. Vertical reference systems are preferably related to the sea level as the accessible part of the geoid. Vertical reference networks are measured not only by spirit leveling but also by GNSS combined with gravimetric measurements.

Historical Reference Systems

In the past, horizontal national reference systems were based originally on triangulation networks, when directions could be measured more precisely with theodolites than distances by rods. Triangulation networks had been oriented by astronomical azimuth measurements, setting the horizontal geodetic datum at the fundamental point. The scale was introduced by baseline enlargement networks.

The error in triangulation networks could reach 1–5 ppm with respect to the distance to the datum reference point. When electronics entered the geodetic instrumentation during the 1960s, electromagnetic signals (microwave, laser) allowed the measurement of distances more precisely than directions. Trilateration networks complemented or replaced the triangulation networks.

The introduction of space geodetic methods in the 1980s, i.e., Navy Navigation Satellite System based on the Doppler effect and the follow-up GPS system, replaced most of the historical national reference systems based on classical triangulation or trilateration methods. The advantages are the global availability and the superior accuracy of the GNSS. The disadvantages are the dependency on the control segment of the GNSS and the availability of energy and communication in order to be able to use it.

The separation of horizontal and vertical reference networks is the consequence of the historical development of the geodetic methods. Modern geodetic space techniques VLBI, SLR, and GNSS are three-dimensional methods and can be used to overcome the classical separation. This becomes possible if the geometrical and geophysical properties of the geodetic observations are modeled correctly in the corresponding reference frame.

Global Geodesy

International Services

The task of global geodesy requires a global infrastructure with geodetic observatories. Institutions in many countries

collaborate voluntarily in the global task to provide terrestrial reference frames by sharing their human, technical and financial resources, observational data, and geodetic products. This work has been initiated under the umbrella of the International Association of Geodesy (IAG). Even today, no country has been capable of reaching the same results on its own. This fact makes the nonprofit-oriented work of international services indispensable to achieve the ITRF and the ICRF. With the UN Resolution 69/266, the former scientific-driven global geodetic networks are complemented by an administrative support through the Committee of Experts on Global Geospatial Information Management (UN-GGIM) in order to enhance the global geodetic networks and improve the unequally available geoinformation infrastructure.

The international services can be classified according to their domains. In the space domain, the following services are the International VLBI Service (IVS), International Laser Ranging Service (ILRS), International Global Navigation Satellite System Service (IGS), and International DORIS Service (IDS). In the time domain, the Bureau International des Poids et Mesures (BIPM) in Paris hosts the office, which is generating the Universal Time (UT) scale as the time base. In the gravity field domain, the International Gravity Field Service (IGFS) with its Technical Support Center (IGFS-TSC) forms the umbrella for the Bureau Gravimétrique International (BGI), the International Service for the Geoid (ISG), the International Geodynamics and Earth Tide Service (IGETS), the International Center for Global Earth Models (ICGEM), the Combination Service for Time-variable Gravity Models (COST-G), and the International Digital Elevation Model Service (IDEMS). The International Earth Rotation and Reference Systems Service (IERS) is primarily using the products of the IVS, ILRS, IGS, and IDS for the computation of the ICRF, ITRF, and EOP. All of the services mentioned above are part of the International Association of Geodesy (IAG).

With the development of the geodetic space techniques, it became obvious that an international coordination is beneficial for the users of geodetic products in navigation, land surveying, mapping, and scientific research. Therefore most of the international services were created during the 1990s to continue previously existing project-related collaborations.

The IAG introduced a project called Global Geodetic Observing System (GGOS) as its contribution to the Global Earth Observing System of Systems (GEOSS). GEOSS is an effort of the Group of Earth Observation (GEO), which unifies more than 80 countries and more than 50 international organizations to improve the monitoring and hence the better understanding of global changes. The international services form the backbone for the realization of GGOS. The goal of GGOS is to provide a TRF with a global precision of 1 mm in position and 0.1 mm/yr. velocity determination (Plag and Pearlman 2009). This ambitious goal can only be reached if

more geodetic observatories with the characteristics of a fundamental station for geodesy will be implemented in a more homogeneous global distribution. The international services themselves try to improve their products so that they match the high precision demands of GGOS. This challenges the design of observing networks, improved observation schedules, new instruments and targets, improvements of the data acquisition and processing, and the homogenization and integration of the models of geodetic space techniques.

If the postulated precision can be achieved in the reference frames, trends in global changes will be discovered and resolved in shorter time periods. This compensates partly the lack of long-term monitoring data at many locations on Earth.

Fundamental Station for Geodesy

At fundamental reference points for global reference frames, one encounters the necessary instrumentation for observing in the space domain, in the time domain, and in the gravitational field domain of Earth. These domains correspond to the underlying physical model on which global geodetic reference systems need to be defined.

Each geodetic space method leads to a specific TRF, e.g., VLBI to a VLBI-TRF, SLR to a SLR-TRF, or GNSS to one of the GNSS-TRF. Each one of the specific TRFs contains site positions and velocities of the specific instruments. Each one of the different techniques has some advantages but also weaknesses regarding the realization of reference systems. Geodesists prefer to use all the techniques in a synergetic way in order to minimize the effect of otherwise undetectable systematic errors. Thus, the collocation of different geodetic space technique instruments at some sites is the key to achieve the best TRF. The space geodesy instruments also need to be complemented by local sensors in order to obtain a complete set of observables for the models used in data reduction.

A geodetic observatory in which all relevant space geodetic observation methods are operated is called a fundamental station if it complies with the following characteristics: (a) *permanency* of the operation by consideration of the time scales of geodynamic phenomena and therefore long-term assured production of geodetic data, (b) *complementariness* of the operated geodetic space techniques for the best possible coverage of the system Earth affecting phenomena as to obtain the best possible realization of a precise global reference system, (c) *redundancy* within the selected instruments for quality assurance of the observational data by independently obtained results of the same observables, and (d) *linking* of the technique-specific reference points by their corresponding space vectors, usually determined by a local survey within a local geodetic network, which is also used for the monitoring of the local site stability.

A fundamental station for geodesy enables the link and the transformation from one technique-specific reference frame

(e.g., VLBI) to another (e.g., GNSS) by coordinate transformation. Fundamental stations are constitutive for the realization of the ITRF which is based on observational data produced by VLBI, SLR, GNSS, and DORIS (Hase 1999).

Instrumentation of a Fundamental Station

The concept of a fundamental station was first realized at the Geodetic Observatory in Wettzell, Germany, in 1988. Since then the concept has been applied to other observatory sites, i.e., Ny-Alesund, Yebes, GGAO, Yarragadee, Hartebeesthoek, and AGGO. These observatories operate radio telescopes for geodetic/astrometric VLBI, optical telescopes with a laser system for SLR, and some GNSS receivers at the site plus an additional regional permanent network for monitoring the regional stability in the space domain. At these sites *local geodetic networks* are installed which allow to tie the telescope reference points to the GNSS antenna reference points and hence the individual technique-specific reference frames.

As the geodetic space techniques basically measure time intervals, a fundamental station needs to be equipped with frequency standards defining the time unit: the second. The instrument for the time domain is a time and frequency laboratory, which operates at least three atomic clocks based on frequency standards. Redundancy is an issue in timekeeping instrumentation. Otherwise, drifts in time cannot be related to one specific clock. That is, geodetic observatories may host three cesium normals for long-term time scale generation and up to three hydrogen maser for short-term time interval measurements.

Concerning the gravity field domain, a fundamental station must measure the gravity periodically with an absolute gravity meter and permanently with a superconducting gravity meter in order to determine the Earth tides. The daily gravitational deformations of Earth's crust reach several decimeters which is therefore the largest time variable spatial parameter in intercontinental baseline measurements and needs to be considered in the analysis of geodetic space techniques.

Fundamental stations for geodesy produce observational data in the space, time, and gravitational field domain.

In order to perform the observations correctly or to interpret the measurements afterward, additional local sensors are necessary. Meteorological sensors deliver input data for the application of refraction corrections during observation with the telescopes and compute signal travel times through the atmosphere. Hydrological sensors are requested to model seasonal variations in the gravity data. Laser gyroscopes deliver local Earth rotation parameters (as opposed to global determined EOP by geodetic space techniques), Seismometers deliver epochs of seismic events to model the nonlinearity of continental drift respective to the site motion (Fig. 2).

Geodesy, Networks, and Reference Systems, Fig. 2

The Argentinean-German Geodetic Observatory (AGGO) hosts as a fundamental station for geodesy a radio telescope for VLBI (in the back), a GNSS antenna (on the right), and a SLR telescope (in the front). The invariant points of the telescopes and the phase center of the GNSS antenna are object of a local survey in order to determine the spatial vectors between the reference points of each technique. Only the co-location of complementary instruments and its local survey enable the global reference frames with the quality of the ITRF. AGGO also hosts a time and frequency laboratory for the time reference and a gravity laboratory with absolute and superconducting gravity meter for the geopotential reference (not in this picture)

Summary

The task of geodesy is to establish global geodetic reference systems. These reference systems are defined theoretically in context of the knowledge of physics. Global reference systems are realized by geodetic observatories and measuring reference stations which mark reference points in the space and time domain and in the gravitational field of Earth. Metrology provides the corresponding physical constants and units to be used in the measurements. The cooperative use of the same geodetic method at various measuring platforms creates a geodetic network. A set of observational data from a geodetic network defines a specific geodetic reference frame which relates usually to a specific epoch. Continuous changes of Earth's surface require a permanent monitoring. Different terrestrial reference frames can be tied together by collocating geodetic space techniques.

Fundamental stations for geodesy establish reference points in technique-specific TRF which are tied together by the knowledge of the local spatial vectors between the technique-specific reference points. The ITRF is based on observational data of various space geodetic methods tied in a synergetic manner at collocated and fundamental stations. The WGS84 is based only on GPS observations and coincides with the multi-technique-based ITRF within 1–2 cm. Global change studies drive the global precision of TRF to 1 mm in position and 0.1 mm in point velocity. The International Association of Geodesy undertakes an effort with the Global Geodetic Observing System to set

up the necessary infrastructure and improve the geodetic products.

The use of geodetic satellite methods in positioning requires a precise knowledge of orbital parameters. Two out of six parameters are dependent on the variable Earth's rotation. Monitoring Earth's rotation requires the creation of a Celestial Reference System. The ICRF are based on quasar positions measured by global VLBI networks. The transformation parameters from the space-fixed celestial reference frame to the Earth-bound terrestrial reference frame are given by the time variable Earth orientation parameters (EOP).

Definition

Geodesy is a branch of Earth sciences that deals with the measurement and representation of the Earth's shape and its

gravitational field. Geodesy may be broadly divided into the areas of global (satellite) geodesy, geodetic surveys (national and supranational), and plane surveying (topographic surveying, cadastral surveying). Global geodesy includes the determination of the shape of the Earth, its orientation in space, and its external gravity field. A geodetic survey is for the determination of the Earth's surface and gravity field over a region that typically spans a country or a group of countries. In plane surveying, the details of the Earth's surface are determined on a local scale, and thus the curvature and gravity effects are generally ignored. A close relation exists between the above three areas of geodesy in the sense that geodetic surveys are linked to reference frames established by global geodesy, whereas plane surveys are generally referenced to control points established by geodetic surveys. Physical geodesy utilizes measurements and characteristics of the Earth's gravity field as well as theories relating it to deduce the shape of the geoid (See ► [“Geoid Determination, Theory and Principles”](#); ► [“Geoid Determination, Computational Methods”](#)) and thus the figure of the Earth (Haffman and Moritz 2005). With sufficient information regarding the Earth's gravity field (See ► [“Gravity Field of the Earth”](#)), it is possible to determine geoid undulations (See ► [“Geoid Undulation, Interpretation”](#)), gravimetric deflections, the Earth's flattening and other broad characteristics of the Earth, such as equatorial ellipticity – the C22, S22 terms of the spherical expansion of the gravity field, the C21, S21 terms related to the position of the rotation axis, etc. with a view to their application in geodesy. Recent developments in physical geodesy includes satellite gravity missions (See ► [“Gravity Method, Satellite”](#)), which enables one to map many parts of the world with 1 cm detailed geoid model and determination of global gravity field to 1 mGal accuracy (Sjöberg 2015).

Historical Development of Geodesy

Geodesy is one among the oldest sciences dealing with the planet Earth. Superseding the use of sphere as a model to describe the shape of the Earth, the oblate rotational ellipsoid became widely accepted as the model of choice in the early eighteenth century. The significance of the gravity field was recognized in the nineteenth century leading to the introduction of the geoid (See ► [“Geoid”](#)). Later in the second half of the twentieth century, satellite techniques (See ► [“Gravity Field, Temporal Variations from Space Techniques”](#)) have brought out commendable advancements for realization of three-dimensional concept of geodesy. A drastic increase in the accuracy of geodetic observations required that time variations be taken into account, which in turn leads the development of four-dimensional geodesy. Smith (1986) had given a detailed description on the historical development of geodesy.

Gravity Field of the Earth

A body rotating with the Earth experiences the gravitational force of the masses of the Earth, other celestial bodies as well as the centrifugal force due to the Earth's rotation (See ► “Earth Rotation”). The resultant is the force of gravity (See ► “Gravity Field of the Earth”). If the effects of centrifugal force and that of celestial bodies are removed from gravity, the left-out component is gravitation. Newton's law of gravitation states that the force of attraction between two-point masses m_1 and m_2 is directly proportional to the product of their masses and inversely to the square of the distance separating the centers of respective masses and is given as

$$F = \frac{-Gm_1m_2}{r^2} \frac{k}{r}, \quad (1)$$

where, F is the force on m_2 , r is the distance between m_1 and m_2 , and G is universal gravitational constant. The minus sign represents that the force is always attractive. By setting the mass at the attracted point to unity, the above equation transforms into the gravitational acceleration

$$g = \frac{-Gm}{r^2} \frac{k}{r}. \quad (2)$$

The vector k may be expressed by the position vectors r and r' in the Cartesian coordinate system as

$$k = r - r', r^T = (X, Y, Z), r'^T = (X', Y', Z'),$$

with the magnitude of

$$k = \sqrt{(X - X')^2 + (Y - Y')^2 + (Z - Z')^2}.$$

However, the Earth is composed of an infinite number of differential mass elements, dm . The gravitation on the unit mass results from the integral over the individual contributions. The equation for gravitational acceleration then takes the form

$$g = -G \iiint \frac{r - r'}{|r - r'|^3} dm. \quad (3)$$

The mass element dm can be expressed as

$$dm = \rho du, \quad (4)$$

where, ρ is density of volume element du .

The representation of gravitational acceleration and related computations are simplified if gravity potential (scalar quantity) is used. Because the gravitational field is invariant to rotations

$$\text{curl} g = 0 \quad (5)$$

The vector g may be represented as the gradient of a potential U (Sigl 1985),

$$g = \text{grad} U. \quad (6)$$

For a point mass m , one can write

$$U = \frac{GM}{r}, \text{ with } \lim_{r \rightarrow \infty} U = 0. \quad (7)$$

For the Earth, the potential can be expressed as

$$U = G \iiint \frac{dm}{r} = G \iiint \frac{\rho}{r} du, \lim_{r \rightarrow \infty} U = 0. \quad (8)$$

The potential indicates that the work that must be done by gravitation in order to move the unit mass from infinity to the point under consideration.

From the above relations, it is clear that once the density function ρ is known for the Earth, the gravitation can be calculated as a function of position (See ► “Gravity Modeling, Theory and Computation”). In reality, detailed density information is available for the upper layers of the Earth only (See ► “Earth, Density Distribution”), while global models merely consider radial density changes. Consequently, gravity field observations have to be used in order to model the exterior gravity field (Torge 2001).

Properties of the Gravitational Potential

Gravity potential U satisfies Laplace's equation (Murthy 1998) i.e.,

$$\nabla^2 U = 0, \quad (9)$$

at all points unoccupied by matter. All the space derivatives of this potential also satisfy Laplace's equation. However, at points occupied by matter, gravity potential satisfies Poisson's equation

$$\nabla^2 U = -4\pi Gd, \quad (10)$$

where d is the density at the point under consideration. Green's theorem connecting volume and surface integrations of potential fields has many important applications. If U and U' are two potential functions, whose first derivatives are finite, continuous and single valued throughout a volume v bounded by a closed surface, s , then

$$\int_v (U \nabla^2 U' - U' \nabla^2 U) dv = \int_s \left[U \frac{\partial U'}{\partial n} - U' \frac{\partial U}{\partial n} \right] ds, \quad (11)$$

where n is the direction of the outward drawn normal to the surface. The theorem is independent of the size or shape of the surface or the nature of distribution of masses causing U and U' . If U' is assumed to be constant everywhere and U is the Newtonian potential due to masses distributed both inside and outside the closed surface, s , then

$$\nabla^2 U' = 0, \frac{\partial U'}{\partial n} = 0, \quad (12)$$

reducing equation to the form

$$\int_v \nabla^2 U dv = \int_s \frac{\partial U}{\partial n} ds. \quad (13)$$

If U_{in} and U_{out} are respectively the potentials due to masses inside and outside the surface, s , then U_{out} obeys Laplace's equation while U_{in} satisfies Poisson's equation, i.e.,

$$\int_s \frac{\partial U}{\partial n} ds = -4\pi GM. \quad (14)$$

This is called Gauss' law, which states that the total normal gravitational flux over a closed surface is $-4\pi G$ times the enclosed mass. This law is valid irrespective of the type of mass distribution within the closed surface, s . Basic relationships can therefore be established between the observations in the gravity field and the parameters describing the surface.

Disturbing Potential

The difference between the actual (measured) gravity potential, W , and the normal gravity potential (constructed by matching the known reference ellipsoid with an equipotential surface), U , is called the anomalous or disturbing potential, T (Hoffman and Moritz 2005). The disturbing potential T is numerically smaller than U or W , and captures the detailed, complex variations of the true gravity field of the Earth from point-to-point, as distinguished from the overall global trend captured by the smooth mathematical ellipsoid of the normal potential. The relation between the geoid undulation, N , disturbing potential, T , and the force of gravity (F) computed from the normal gravity potential can be expressed by Bruns' formula as

$$N = \frac{T}{F}. \quad (15)$$

The Stokes' formula which enables one in determining the geoid from gravity data in physical geodesy can be expressed as

$$N = \frac{R}{4\pi F} \iint_{\sigma} \Delta g S(\Psi) d\sigma. \quad (16)$$

Here, Δg stands for gravity anomalies, and $S(\Psi)$ is the Stokes function derived by Stokes in a closed analytical form.

Geoid and Reference Ellipsoid

The equipotential surface of the Earth's gravity field that coincides with the Mean Sea Level (MSL) in the absence of currents, air pressure variation, etc. is called the geoid (See ► [“Geoid”](#)). Most of the efforts in physical geodesy are concentrated on the geoid determination with steadily increasing accuracy (Heiskanen and Moritz 1967, See ► [“Geoid Determination, Theory and Principles”](#)). The geoid is important for understanding more about ocean currents and is also used as a reference for traditional height systems and monitoring sea-level change. However, as in the case of any other equipotential surface of the Earth's gravity field the geoid surface is also an irregular surface and too complicated to serve as the computational surface. The mathematical surface that best fits the geoid is the reference ellipsoid. The relation between the geoid and the ellipsoid is shown in Fig. 1. The ellipsoid lies below the geoid surface in elevated regions and above the mean sea level (MSL) over the oceans. The geometrical separation between the geoid and the reference ellipsoid is called the geoid undulation, N (See ► [“Geoid Undulation, Interpretation”](#)), which generally varies globally between ± 110 m.

Gravity measurements are used in physical geodesy to determine the figure of the Earth (See ► [“Geodesy, Figure of the Earth”](#)). The justification in equating the Earth's shape to a model other than that of a sphere can be found from two observations, namely, (i) for a rotating sphere having uniform radius R and angular velocity ω the gravitational attraction at the equator and pole should differ by $R\omega^2$. For the values of R and ω relevant to the geoid, this figure works out to be 3.4 gals as against the observed value of 5.17 gals in gravity values at the equator and the pole. This discrepancy suggests an appreciable departure of the mean shape of the geoid from that of a sphere, also (ii) arc measurements at the pole and equator showed that the meridian degree at the pole is longer than that at the equator. The centrifugal acceleration causes the Earth's surface to flatten at the poles and to bulge at the equator. These effects would adequately explain the observed discrepancy in the difference of gravity at the equator and pole. It is thus reasonable to equate the Earth's shape to that of an oblate ellipsoid. The Earth's gravity field on the ellipsoidal surface varies only with the geographic latitude, φ , and is defined by the International Gravity Formula (Wilcox 1989, Also see ► [“International Gravity Formula”](#))

$$g(\varphi) = 978.0327(1 + 0.0053024 \sin^2 \varphi - 0.0000058 \sin^2 2\varphi) \text{ cm/s}^2.$$

Geodesy, Physical,**Fig. 1** Relation between Earth's topography, geoid and reference ellipsoid**Methods of In Situ Measurements**

Two distinctly different types of gravity measurements are made: absolute gravity measurements and relative gravity measurements. If the value of acceleration of gravity can be determined at the point of measurement directly from the data observed at that point, the gravity measurement is absolute (See ► [“Gravity Measurements, Absolute”](#)). If only the differences in the value of the acceleration of gravity are measured between two or more points, the measurements are relative (See ► [“Gravity Method, Surface”](#)). The most important gravity field quantities measured on the Earth's surface are gravity potential differences determined by leveling in combination with gravity measurement; the modulus of the gravity vector determined by absolute and relative gravity measurements; the direction of the gravity vector determined by geodetic-astronomical observations; and the components of the second-order gravity gradient tensor determined by torsion balance measurements.

Satellite Geodesy

Satellite geodesy utilizes artificial satellites and the moon as extraterrestrial targets or sensors. For a point mass Earth model, the orbital motion of a satellite is described by Kepler's laws. The actual gravitational field and nongravitational forces create orbital perturbations. Satellites used for geodetic applications differ in design, equipment, and orbit according to the respective observation technique and the mission purpose. Classical measurement methods based on orbital perturbations, introduced and employed from 1960s to 1980s demonstrated the efficacy of satellite observations for establishing large region geodetic control networks and gravitational field determination (See ► [“Gravity Method, Satellite”](#); ► [“Gravity Field, Temporal Variations from Space Techniques”](#)). Now the Global Positioning System (GPS) has become the most important method for a

fast and precise determination of geodetic positions (See ► [“GPS, Data Acquisition, and Analysis”](#); ► [“Geodesy, Ground Positioning, and Levelling”](#)). Today, the GPS governs three-dimensional positioning at all scales while laser distance measurements primarily contribute to global reference networks (See ► [“Geodesy, Networks, and Reference Systems”](#)). By monitoring the ocean surface, satellite altimetry contributes to gravity field modeling, and high-resolution global gravity recovery is now possible from satellite-to-satellite tracking and gravity gradiometry missions (e.g., GRACE and GOCE missions). The theory of satellite orbits and measurement methods was described in detail by Seeber (1993) and Kaula (1966).

Determining the Geoid

An intimate relationship exists between the height of the geoid, the Earth's gravitational attraction, and the distribution of mass within the Earth. The shape of the geoid does place important constraints on the mass distribution. Moreover, since the local vertical is defined as the direction of the gravitational attraction, which is always perpendicular to the geoid, geoid anomalies cause deflections of the vertical, which are of vital practical importance for surveyors. Determining the geoid is therefore an important objective in geodesy and geophysics.

In the presatellite era, the geoid was determined from the gravity field, which entailed measuring gravitational attraction or deflections of the vertical (or both) at a large number of locations around the Earth. Accuracy and resolution were limited by the number and distribution of observations that were feasible. Since the advent of artificial satellites, geoid determinations have become easier, more accurate, and of even higher resolution (See ► [“Geoid Determination, Computational Methods”](#); ► [“Geoid Determination, Theory and Principles”](#); ► [“Gravity Method, Satellite”](#)). Since the early 1980s, the mean sea level (or oceanic geoid) has been measured directly

by a radar-altimeter mounted on a satellite. It is important to remove the effects of waves, storms, ocean currents, and other similar effects, but ultimately this method gives a precision of a few centimeters in geoid height. Although they cannot be used over land, such measurements have yielded unprecedented high-resolution coverage of the geoid over the sea (Rapp 1982a, b; Sandwell and Schubert 1982; Cazenave and Monnereau 1987; Wunsch and Stammer 1998; Fu and Cazenave 2001). Besides, satellite gravity data is found to have tremendous applications, particularly in structural mapping, and modelling of large-scale geologic features in both onshore and offshore regions. However, it should be realized that the gravity data obtained from satellite altimetry is more reliable at longer wavelengths than at shorter wavelengths (Green et al. 2019). During 1980s and 1990s, Geosat and ERS-1 had been used to obtain high resolution marine geoid; and since 2010, the Cryosat-2 mission also has gained importance for measuring high resolution sea surface topography (Sandwell et al. 2014). In recent past, under the NASA Earth System Science Pathfinder (ESSP) Program the GRACE mission was developed in collaboration with the German Space Agency to accurately map the temporal variations in the Earth's gravity field. The mission launched in 2002 has provided the scientists an efficient and cost-effective way to map the Earth's gravity fields with high accuracy. The results from this mission has yielded crucial information about the distribution and flow of mass within the Earth and its surroundings. The gravity variations measured by GRACE has yielded important information on ice mass change over ice sheets and glaciers, ocean mass change due to land ice melt, and changes in terrestrial water storage over the continents (more details on the mission can be found at <http://www.csr.utexas.edu/grace>).

Further, satellite gradiometer mission (See ► “Gravity, Gradiometry”) named as Gravity field and steady-state Ocean Circulation Explorer (GOCE) was designed and launched by the European Space Agency (ESA) to determine gravity field anomalies with an accuracy of 1 mGal, and geoid with an accuracy of 1–2 cm. GOCE has provided gravity field data with unparalleled accuracy and spatial resolution during its life time between 2009 and 2013. The final gravity map and model of the geoid will provide users worldwide with a well-defined data product that will lead to a better understanding of the physics of the Earth's interior to gain new insights into the geodynamics associated with the lithosphere, mantle composition and rheology, uplift and subduction processes, a better understanding of the ocean currents and heat transport, a global height-reference system, to serve as a reference surface to study topographic processes and sea-level change, better estimates of the thickness of polar ice-sheets and their movement. Further details of the mission can be found at http://www.esa.int/esaLP/ESAYEK1VMOC_LPgoce_0.html.

Gravity Reduction

Gravity measurements provide values for the acceleration of gravity at points located on the physical surface of the Earth. Before these measurements can be used for most geodetic purposes, they must be converted into gravity anomalies. Gravity measured on the physical surface of the Earth must be distinguished from normal gravity referring to the surface of the reference ellipsoid. The measured gravity values show point to point variation on the Earth's surface because the measured field depends on latitude and elevation of the station and also due to the effects of topographic masses above sea level (Murthy 1998). The important corrections to the measured gravity data include latitude or normal correction, free-air correction, Bouguer correction, topographic correction, and isostatic correction (See ► “Gravity, Data to Anomalies”). The latitude correction calculates the normal gravity on the ellipsoidal surface, the free-air correction extrapolates it to the level of observation, the topographic and Bouguer corrections account for the gravity effect of the material between the geoid and the ground surface. Isostatic correction removes long-wavelength variations in the gravity field inversely related to topography. The magnitudes of these corrections more often equal to the measured field itself and therefore should be evaluated carefully and precisely.

Gravity Models

Two important models are in vogue (i) effect models and (ii) source models (Sunkel 1989). Effect models deals with the calculation of four parameters to define the best fitting ellipsoid to the shape of the Earth. These parameters are the product of the gravitational constant and the total mass of the Earth, a dimensionless dynamical form parameter in terms of a second degree spectral coefficient of the Earth's gravity field which is closely related to the flattening of the ellipsoid of revolution, the equatorial radius, and the angular velocity. However, the surface defined by the above parameters describes the global feature of the shape of the Earth and its gravity field (See ► “Geoid Determination, Computational Methods”; ► “Gravity, Global Models”). For more elaborate models, spherical harmonic coefficients have to be derived from surface and satellite data (Rapp and Cruz 1986). Ditmar et al. (2003) discussed the regularization issues of the computation of spherical harmonic coefficients of the gravity gradiometric data acquired by the GOCE satellite. On the other hand, source models presume a density model having radically changing but laterally constant mass density. Such a density model can be described by a few parameters and can therefore be compared with an ellipsoidal model.

Conclusions

The gravity field of the Earth, which forms the backbone for the studies relating to geometrical geodesy and physical geodesy, can be described in terms of potential, its derivatives both vertical and horizontal in several scales involving global, regional, and/or local information. The gradiometer missions will probably replace, even though not fully but to a large extent, the surface observations thereby pave the way for more detailed information on geoid with unprecedented accuracy.

Geodetic Pendulums, Horizontal Ultra Broad Band

Carla Braitenberg

Department of Mathematics and Geosciences, University of Trieste, Trieste, Italy

Synonyms

Ultra broad band long base tiltmeter

Definition

The ultra broad band horizontal geodetic pendulum is a device designed to measure the earth crustal movement in the range of periods typical of secular movements to seismic deformations. It measures the variation of the plumb line (vertical) with respect to the direction of two earth-fixed reference points (Zadro and Braitenberg 1999).

Instrument Description

The vertical pendulum is made of a mass suspended by a rod or wire that can oscillate in the vertical plane about a horizontal axis. For small amplitudes the oscillation period T depends on the moment of inertia K , the distance s of the center of mass from the rotation axis, the mass m , and the gravity acceleration g following the equation $T^2 = \frac{4\pi^2 K}{mgs}$. If the pendulum is allowed to oscillate about an inclined axis, the angle of the rotation axis with the vertical being ϕ , the period of oscillation is defined by $T^2 = \frac{4\pi^2 K}{\sin \phi mgs}$. For small values of the angle ϕ , the rotation axis is near to vertical, and the pendulum is called horizontal pendulum. Compared to the vertical pendulum of equal dimensions, the horizontal pendulum has an increased oscillation period. The first realizations of a horizontal pendulum were done in 1830 (Lorenz Hengler) and developed further by Zöllner (Zöllner 1871, 1872). The construction of Zöllner is made of a horizontal rod on which at one end a mass is attached. At the other end and at a small distance from it, the rod is connected by two wires to a housing structure (see Fig. 1). The two wires are near to vertical above each other. Supposing the upper fixed point is shifted with respect to the lower fixed point along the Meridian, so that the line connecting the two fixed points makes an angle ϕ with the vertical, then the rod has its equilibrium position in the Meridian plane. If the direction of the vertical changes due to the influence of the gravitational attraction of the moon or sun toward east by a small angle α , the rod will

rotate toward east by the angle $\frac{\alpha}{\sin \phi}$. A similar rotation of the rod will be produced by the inclination of the housing structure or by a horizontal eastward movement of the housing structure as could be provoked by the passage of a seismic wave. In order to have an instrument sensitive in both NS and EW directions, usually a couple of orthogonally mounted pendulums is installed at one station. The movement of the rod is recorded by a space-sensitive device, as a magnetic induction coil mounted at the extreme of the rod or by an optical device that records the light ray reflected by a mirror mounted on the rod (e.g., Braitenberg et al. 2006).

Grotta Gigante Horizontal Pendulums

The largest prototype of a horizontal pendulum was built in 1959 by Antonio Marussi (Marussi 1959) in a natural cave (Grotta Gigante) situated in the Italian Karst at 275 m above sea level near the town of Trieste, Italy. Trieste is a port on the Adriatic Sea, 150 km East of Venice. The upper and lower wires of the horizontal pendulum-rod are fixed directly into the rock, at a vertical distance of 95 m. The oscillation period of the pendulum is near to 6 min, and damping is critical. The original recording of the pendulum was on a photographic paper, which was changed to a digital system in the year 2002. The instrument is very stable, and records multi-decennial crustal movements. The digital system has a sampling rate of 25 Hz, which makes it possible to observe fast movements of

Geodetic Pendulums, Horizontal Ultra Broad Band, Fig. 1

Cartoon of a horizontal geodetic pendulum. The rod with the mass rotates in the horizontal plane about the virtual rotation axis. The angle ϕ of the virtual rotation axis with the plumb line is essential for the amplification factor of the pendulum

the pendulum caused by the passage of seismic waves. The smallest resolved tilt is 0.009 nrad (1 nrad = 10^{-9} rad).

The continuous record of tilt extends from 1966 to the present and demonstrates that the cave deforms continuously due to very different causes that act independently from each other. Each generates a characteristic signal contributing to the complex deformation of the cave. The graph in Fig. 2a displaying the entire tilt sequence shows a secular drift that adds to an oscillation with a period of 33 years. The long-term movement is a tilt of the cave toward NW, parallel to the coastline, and is probably tied to a deformation of the Adria plate that is bent below the load of the sediments in front of the South Alpine mountain chain. The cause of the multi-annual oscillation is presently unknown and could be tied to large-scale deformations imposed by the active deformation due to the collision of the Adria and the Eurasian plate, causing the seismicity at the contact between the sedimentary plain and the South Alpine mountains. The tilting of the cave with an annual period (mean period = 365.6 days and mean amplitude = 300 nrad for years 1966–2008; oscillation amplitude defined as half the peak-to-peak signal) has a characteristic orientation with extreme values in mid September and mid March. The annual tilting is due to the combined effect of the deformations due to the annual surface temperature variations (sinusoidal with an amplitude of 9.2 °C) and to the variable loading of the Adriatic Sea.

The earth tides generate a tilting that is due to the regular deformation of the earth in response to the gravitational attraction of moon and sun, with predominantly diurnal and semidiurnal periods. The amplitude of the earth tide tilting is 39 nrad, and the gravitational attraction and the load of the ocean tide contribute to an additional tilt signal at the same tidal frequencies but phase shifted with respect to the astronomical earth tide, leading to a total tidal tilting signal with a maximum amplitude of 90 nrad. The fault rupture of an earthquake leads to the generation of the well-known seismic waves that propagate along the earth surface and through earth's interior. Another movement caused by earthquakes is the oscillation of the earth at its resonance frequencies, called the free oscillations. The crustal rupture causes the earth to pulsate in the spherical and torsional oscillation modes. The gravest spheroidal mode 0S2 where the earth deforms with an ellipsoidal pattern has a 54-min period, the more complicated modes having shorter periods. The gravest torsional mode 0T2 has a period of 43.9 min, one earth hemisphere rotating with respect to the other around a central axis (Bolt and Marussi 1962). The geodetic pendulums of the Grotta Gigante station are the only instruments in the world that recorded the free oscillations generated by the greatest ($M = 9.5$, Chile, 1960; NEIC 2010), third greatest ($M = 9.1$, Sumatra Andaman Islands, 2004; NEIC 2010), and fifth greatest earthquake ($M = 8.8$; Chile, 2010; NEIC 2010) ever recorded in

instrumental seismology. The observations showed that the amplitude of the free oscillations of the Chile 1960 earthquake were up to four and a half times greater than those generated by the Sumatra-Andaman 2004 event (Braitenberg and Zadro 2007), the greatest enhancement being found for the torsional modes (see spectrum in Fig. 2b). The cave deforms not only due to periodic signals, similar to the ones we described before, but also due to transients, as pressure variations and underground water flow. The underground water flow is particularly interesting in karstic areas: The water from rainfall penetrates into the rock through pores and cracks until it finds an impermeable layer along which it flows downstream toward the sea. The Italian Karst is particular in this respect, as an entire surface river with an average flow of 9 m³/s reaching peaks of 100 m³/s during strong rainfalls, with extreme values up to 390 m³/s, disappears after its passage through a natural cave (Skocjanske Jame 2010). The underground river remains concealed for 33 km, until it emerges as a spring from the foot of the Karst and flows into the Adriatic Sea. The path of the flow is unknown, but its presence is identified by the geodetic pendulums. The cave responds in a characteristic direction to floods, with a signal that lasts in total between 4 and 8 days. The length of the deformation is indicative of the time the underground river takes to accommodate for the increased influx of water through the rainfall. The hydrologic-induced tilt signal is up to 300 nrad according to the existing records and is accompanied by uplift, as has been observed by GPS. The deformation is generated by an overpressure in the water-filled karst channel system (Braitenberg et al. 2019). Table 1 summarizes the different causes that generate a tilting of the cave together with the expected amplitude.

Besides the horizontal geodetic pendulums, other types of instruments exist with which tilt is observed. In the horizontal water tube, the differential water level at each end of the tube is measured by laser interferometry (e.g., Ferreira et al. 2006). The length of the tube extends over several tens of meters. Presently active instruments are found, e.g., at the Finnish Geodetic Institute, Metsähovi mine (Ruotsalainen 2008, 2018), and in California (Piñon Flat Observatory, University of California, San Diego). Vertical pendulums are mounted in boreholes for measuring tilt and the displacement of the pendulum is detected by a capacitive transducer with resolution of 1 nrad; examples are the tiltmeters of the Geodynamic Observatory Moxa, Thuringia, Germany. The application of a tilt array of this type to monitor pore pressure variations and minor earthquakes is given by Jahr et al. (2008). Portable short-base tiltmeters are used for volcanic monitoring, where the expected tilts are larger than for crustal deformation studies and therefore require less resolution and stability in time. The electronic tiltmeters record the movement of an air bubble in a conducting fluid. These instruments are used for volcanic monitoring of the USGS.

Geodetic Pendulums, Horizontal Ultra Broad Band, Fig. 2 (continued)

Geodetic Pendulums, Horizontal Ultra Broad Band, Fig. 2 The graph shows the continuous time series of tilt recorded by the horizontal geodetic pendulum of Grotta Gigante. (a) *Black continuous lines* are the NS and EW records with daily sampling. The regular oscillation is the annual tilting. The multi-decadal variation is the sum of an oscillation of 31 years (*thick line*) and a linear variation (*dashed line*). The spikes are due to tilting caused by floods of the underground karstic water flow. Asterisks mark data interruptions. (b) Spectral amplitudes in the

frequency range of the free oscillations following the earthquakes of Chile 1960 (CHI-NS, CHI-EW) and Sumatra-Andaman 2004 (SU-NS, SU-EW). (c) The tilting of the cave due to the underground flooding: The *thick line* shows tilting of the cave during the flood and the z-axis is the time. The *thinner line* shows the tilting during the flooding in the EW and NS direction. Furthermore, the water level in a nearby cave during a flood is shown

Geodetic Pendulums, Horizontal Ultra Broad Band, Table 1 Identified causes that deform the Grotta Gigante cave with characteristic periods and amplitudes

Cause of deformation	Characteristic period	Tilt maximum observed amplitude	Notes
Plate tectonics secular movement	Secular movement, near to static	31 nrad/year	
Plate tectonics multi-annual oscillation ^a	31 years	480 nrad	
Annual variation ^a	365.6 days	300 nrad	Orientation toward N60°E in mid March and toward N240°E in mid September
Earth tides ^a	Daily, half daily	39 nrad	
Ocean loading ^a	Daily, half daily	60 nrad	
Free oscillations ^a of the earth	54 min to a few minutes	Up to 0.7 nrad	
Underground water flow	A few days	Up to 300 nrad	

^aOscillation amplitude defined as half of the peak-to-peak excursion

Summary

The ultra broad band horizontal geodetic pendulum measures the inclination of a reference axis with respect to the vertical. The prototype installed in the Giant Cave in Northeastern Italy has shown that the deformations that affect the upper

crust are due to tectonic effects (seismic waves, free oscillations of the earth, coseismic deformation, tectonic plate deformation) and due to environmental effects (thermoelastic deformation, hydrologic water flow, ocean loading). The existing record of the greatest seismic event ever measured, the Chile 1960 earthquake, allows to make an absolute

magnitude comparison with recent events due to the fact that amplitude factor, the instrumental setup, and the location are perfectly known and controllable today.

Geodynamics

Alessandro M. Forte

Department of Geological Sciences, University of Florida, Gainesville, FL, USA

Definition

Geodynamics (noun, functioning in the singular). A broad, multidisciplinary branch of geophysics that investigates the causes and consequences of the forces acting on and inside the solid Earth and the rock movements and deformations they produce.

Geodynamic, Geodynamical (adjective). Relating or pertaining to the field of geodynamics.

The term geodynamics originates from two root words: “geo,” from the Greek *gē* meaning “earth,” and “dynamics,” from the Greek *dynamis* meaning “power.” Dynamics is a branch of physics, based on Newton’s second law of motion, which involves the study of forces acting on bodies and the resulting changes in their motion. As the name therefore suggests, the focus of geodynamics is on the forces that act on the solid Earth and the motions and deformation they produce.

Historically, in the late nineteenth and early twentieth century, when geodynamics was emerging as a distinct field of study, it also included the earliest systematic investigations of earthquakes and propagating seismic waves. These studies later evolved into a separate branch of geophysics called seismology. Modern geodynamics investigates forces and movements over time scales that exceed the characteristic periods of propagating earthquake waves and corresponding Earth oscillations (i.e., approximately ranging from a second to an hour). On longer time scales, for geodynamic processes ranging from Earth tides (hours to years) to glacial isostatic

adjustment (thousands of years) and ultimately plate tectonics (millions of years), the changes in applied forces and the resulting deformations are sufficiently slow that acceleration is entirely negligible (i.e., the deformation of the solid Earth is quasistatic).

The forces studied in geodynamics mainly originate from lateral changes in density $\Delta\rho$ on or within the Earth, thereby producing buoyancy or Archimedes forces $\Delta\rho g$ per unit volume, where g is Earth's gravitational field. For example, lateral density variations in anomalously hot or cold regions in the convecting mantle give rise to buoyancy forces $\Delta\rho g = -\alpha\rho\Delta Tg$, where α is the coefficient of thermal expansion and ΔT is the temperature anomaly relative to the ambient mantle. These thermal buoyancy forces drive the convective circulation in the mantle and the corresponding surface motions of the tectonic plates. Similarly, the topographic depressions Δh at the Earth's surface left behind by the rapid melting of the massive ice sheets that once covered Canada and Scandinavia about 20,000 years ago give rise to buoyancy forces $\Delta h\rho g$ per unit area that act on the surface (here ρ is the average density of the crust). The subsequent glacial isostatic response to this surface force involves slow viscous creep of the mantle and the resulting uplift of the crust in formerly ice-covered regions.

There are also external forces $\rho\nabla\varphi$ where, for example, $\nabla\varphi$ is the gradient of the gravitational potential generated by the attraction of the Sun and Moon, or it may represent the centrifugal force due to Earth's diurnal rotation. For the former case, these forces produce the tidal deformations in the Earth, or, for the latter case, they produce the oblate ellipsoidal shape (i.e., pole-to-equator "flattening") of the Earth. These tidal and rotational forces change over an enormous range of time scales: from 12 h to 18.6 years for tidal forcing and from thousands to hundreds of millions of years for rotational forcing. Tidal and rotational forces produce globally distributed deformations throughout the Earth's interior and at the surface.

A major area of geodynamics research is the measurement and quantitative modeling of forces and corresponding deformations in the crust, lithosphere, and deep mantle. An understanding of the relationship between force and deformation requires detailed knowledge of the rheology of the solid Earth that depends on the ambient temperature, pressure, and the time scales over which the forces are applied. For example, on time scales corresponding to the tides, the solid Earth behaves as an imperfectly elastic body. However, on the much longer time scales of mantle convection and plate tectonics, the solid mantle behaves as a fluid characterized by an effective viscosity that is extremely high.

The effective viscosity η of the mantle is one of the most important parameters in geodynamics because it controls the speed at which the mantle may flow and deform in response to buoyancy forces. The characteristic flow speed is

$v = \Delta\rho gLD/\eta$ where L represents the lateral dimension (horizontal distance) of the density anomalies and D is their vertical dimension (depth extent). Flow velocities in the mantle are of the order of several centimeters per year, similar to those of the moving surface plates. This flow velocity determines the efficiency of convective heat transport across the mantle and hence governs the thermal (and chemical) evolution of the Earth. For this reason, a great deal of work in the second half of the twentieth century, and up to the present day, is focused on constraining the value and spatial variation of mantle viscosity from the analysis of various geodynamic data sets (e.g., from postglacial uplift rates, geoid anomalies, long-term sea level variations, plate motions) as well as from theoretical and experimental studies of the creep properties of mantle minerals (e.g., Karato 2012).

The range of geophysical phenomena studied in geodynamics has increased greatly over the course of the twentieth century. For example, an early treatise on geodynamics by Love (1911) provided a detailed mathematical description of a range of problems that included the isostatic support of continents, the height of mountain chains and the forces required to maintain them, the Earth tides, the propagation of earthquake waves, and the oscillations of the entire Earth produced by earthquakes. With the advent of plate tectonics and the acceptance that some form of thermal convection in the mantle is necessary to drive the plate motions, the scope of geodynamical investigations has been greatly enlarged.

Modern geodynamics research deals with a multitude of problems relating to plate tectonics, heat and mass transfer and chemical mixing in the solid Earth, the rheology and dynamical coupling of the mantle and crust-lithosphere systems, and the impact of internal dynamics on surface geophysical and geological processes. The wide range of problems now included in contemporary geodynamics is well illustrated by Turcotte and Schubert (2014). Depending on the specific problem, it is difficult, if not impossible, to devise analogue laboratory experiments that can properly incorporate the complex spatial variations of the physical properties of the solid Earth. This difficulty is further compounded when it is necessary to model geodynamic processes over extremely large spatial and temporal scales, as in the case of mantle convection and plate tectonics.

To address these major challenges, the rapidly growing field of *computational geodynamics* has emerged, in which complex problems in solid Earth dynamics are now routinely solved on high-performance computers using numerical methods (e.g., Ismail-Zadeh and Tackley 2010; Gerya 2019). The need to develop robust, reliable, and openly accessible implementations of advanced computational algorithms to solve outstanding problems in geodynamics has motivated the growth of community-driven consortia of researchers, such as the "Computational Infrastructure of

Geodynamics” (<https://geodynamics.org/>) that maintains and disseminates open-source software packages for a wide range of applications in crystal dynamics, tectonics, mantle convection, and magnetohydrodynamics in the core.

Geoelectromagnetism

Antal Adam and Laszló Szarka
Geodetic and Geophysical Research, Institute of the
Hungarian Academy of Sciences, Sopron, Hungary

Definitions and Scope

Geoelectromagnetism, in the broad sense, includes the application of classical electrodynamics to various interrelated regions of space (Sun, interplanetary field, magnetosphere, ionosphere, atmosphere), on and below the Earth surface

(near-surface regions, crust, upper mantle [or lithosphere and asthenosphere using alternative nomenclature], lower mantle, and Earth’s core). Over the Earth surface the dominant phenomena of geoelectromagnetism are electromagnetic waves, in a wide spectrum. The electromagnetic waves do not penetrate deep into the Earth. Instead, the propagation of the electromagnetic field inside the Earth is a diffusion process.

In a narrower sense, geoelectromagnetism means the application of time variations of natural electromagnetic fields to the study of the electric resistivity distribution in the Earth’s interior, which gives indispensable information about the structure, composition, and processes of the subsurface.

The term electromagnetic geophysics is also used, but electromagnetic geophysics in general includes all exploration techniques, which may employ not only natural sources, but various man-made sources as well. In order to investigate very deep structures, extremely large-size sources of natural electromagnetic field variations should be used. In the following, we restrict ourselves to those geoelectromagnetic methods that apply natural electromagnetic field variations as the source to study deeper (lithosphere, asthenosphere, and upper mantle) geological structures.

Introduction

Of three electromagnetic parameters (magnetic permeability, electrical resistivity, and permittivity) associated with the subsurface geology, only the magnetic permeability and the electrical resistivity are relevant because of the diffusive nature of the electromagnetic field propagation. The magnetic permeability is usually assumed to be constant, which – apart from some exceptional cases – has been seen to be a good assumption. The electrical conductivity s of various earth materials varies over an extremely wide range; therefore, its spatial distribution reflects most structural/physical/petrological changes in the Earth. In practice, instead of the conductivity, the electrical resistivity ρ , where $\rho = 1/\sigma$, is often used. The ohm-meter (or Ωm) is the unit of measurement.

These methods are classified on the basis of the measured geoelectromagnetic field components. When only the electric field variations are measured, we speak about the *telluric* or *Earth current* technique, or *tellurics* (TT) for short. If only the geomagnetic field components are measured (usually as a function of the period of the time variations of the electromagnetic field), the method is known as “*Geomagnetic Deep Sounding*” (*GDS* for short), or by its other name: “*MagnetoVariation Sounding*” (MVS). Electrical conductivity anomalies (i.e., the zones of concentration of electric current) can be located by using the so-called “*MagnetoVariation Profiling*” (MVP), where the so-called induction vectors point to the current concentrations. A more sophisticated technique is the “*Magnetotelluric Sounding*” (MTS) or

shortly “*magnetotellurics*” (MT), where both the electric and magnetic field variations are measured in a broad period range (see ► “[Magnetic Data Enhancements and Depth Estimation](#)”).

Although the Geomagnetic Deep Sounding (the MagnetoVariation Sounding) is more or less coeval with observatory records (see, e.g., Lamb 1883), the history of almost all these variants dates back to about six decades. The MVP and its induction vectors were introduced in the second half of 1950s in studying the anomalous behavior of geomagnetic variations in North Germany (e.g., Schmucker 1959; Wiese 1965). The theoretical basis of the magnetotelluric (MT) method was laid by Tikhonov (1950) and Cagniard (1953). The first MT field measurements were carried out in the early 1960s. Application of the tellurics (i.e., the simplest technique) to investigate large sedimentary basins started in the middle of the twentieth century in Hungary (Kántás 1954) and elsewhere.

In the following, the principles of these geoelectromagnetic methods will be presented. We summarize the governing equations of MVS, MVP, and MT techniques and illustrate their field application. The telluric measurements being the special case of the magnetotelluric method used in the so-called S-interval (see Fig. 4) where the phase approximates zero, is not discussed here in detail.

Magnetovariational Sounding (MVS) and Magnetovariational Profiling (MVP)

By simultaneously measuring the time variations of the horizontal and vertical geomagnetic field components at a site, it is possible to determine the subsurface electrical resistivity. Carrying out the measurements in a broad period interval, the depth-dependence of the electrical resistivity can be estimated (see ► “[Magnetic Data Enhancements and Depth Estimation](#)”).

For a spherical Earth, this technique is able to provide information about the Earth’s conductivity down to the depths of 1,200–1,800 km in the mantle (Bailey 1973; Rokityansky 1982). For shallower studies (i.e., down to depths of less than approximately 100 km) the Earth’s surface may be considered as plane.

The magnetovariational profiling (MVP) aims at locating large lateral inhomogeneities of the Earth’s crust and upper mantle. In the recent book by Berdichevsky and Dmitriev (2008), this theme is discussed in detail under the title “*Magnetovariation Studies*.”

Deep Mantle MVS Studies

We follow Rokityansky (1982) nomenclature concerning the deep mantle studies. The field source of so-called Dst geomagnetic variations (used recently by Yu Semenov et al. 1997; Yu Semenov et al. 2008) is the ring current at the

equator. When the vertical magnetic field of the ring current source is approximated by the first term in its spherical harmonic expansion, that is, $H_z \tilde{P}_1^0(\cos \theta)$ where $\tilde{P}_1^0$ is the associated Legendre function in the first term of the expansion, the ratio of vertical (H_z) to horizontal ($\sqrt{H_x^2 + H_y^2}$) field component can be converted into the complex apparent resistivity (Rokityansky 1982). (In standard practice, x and y are the horizontal components, with the x -axis pointing northward, and the positive z -axis directed vertically downwards into the ground.) If the magnetic permeability (μ), the radius of the Earth (R), the geomagnetic colatitude of an observatory (Θ), and the angular frequency (ω) in the assumed time-dependence $e^{i\omega t}$ are known, then the apparent resistivity ρ is given as

$$\rho(\omega) = \frac{i\omega\mu}{4} R^2 \tan^2 \Theta \left| \frac{H_z(\omega)}{\sqrt{H_x^2 + H_y^2}} \right|^2.$$

Yu Semenov et al. (1997) used the daily mean values of geomagnetic observatories. Their first step in the analysis was a rotation of the observatory reference systems to determine the maximum Dst field (Schultz and Larsen 1983). For the agreement between the horizontal Dst field and the first spherical harmonic model of the source, a coherence test was carried out. The period ranges, which were in contradiction with the source model, were excluded from further analysis. The transfer functions between the vertical (H_z) and horizontal $\sqrt{H_x^2 + H_y^2}$ components were computed only if the coherence values were greater than 0.7 between them. The transfer functions were converted into apparent resistivity. Yu Semenov et al. (1997) combined the magnetovariational data with the results of magnetotelluric sounding in observatories and estimated, by using a robust technique, the resistivity model below the observatories. The mean geoelectric structure of the mantle below the Pannonian Basin is shown in Fig. 1 on the basis of data from Nagycenk, Litke (Hungary), and Hurbanovo (Slovakia). A more detailed combined MV + MT study in East-Central Europe pointed out a significant difference in the Precambrian and Phanerozoic mantle structures, separated by the Tornquist-Teisseyre Zone (TESZ line; Yu Semenov et al. 2008).

Schmucker (2003) proposal for the generalized horizontal spatial gradient method (gSHG) is promising for a reliable combination with the MT method as stated recently by Vozar and Semenov (2010) modeling. Kelbert et al. (2009) inverted long period geomagnetic response functions to derive a global-scale 3D model of electrical conductivity variations in the Earth’s mantle. Their results – one order magnitude conductivity increase in the subduction zones – support the presence of at least some water in these transition zones.

Geoelectromagnetism, Fig. 1 The mean geoelectrical structure of the mantle in the Pannonian Basin using the magnetic records of Nagycenk, Litke (Hungary), and Hurbanovo (Slovakia) for magnetovariational soundings (Yu Semenov et al. 1997)

Magnetovariational Profiling

It is evident from the Biot–Savart law that on the surface, just over and near the center of a horizontal lineament of high electrical conductivity in the subsurface, in which the telluric currents are gathered, the measured vertical magnetic component H_z is zero. More precisely, H_z is changing sign along a profile, crossing the lineament. At the same time, the horizontal component $\sqrt{H_x^2 + H_y^2}$ has a maximum over the lineament, with a moderate decrease on both sides. Therefore, the $H_z/\sqrt{H_x^2 + H_y^2}$ ratio can be drawn as a vector, that is, a quantity having magnitude and direction. It is called “induction vector” or “induction arrow.” Along a measuring profile crossing the lineament, the induction arrow will change sign. Induction arrow profiles at various periods provide useful depth information. The origin of the method goes back to the resolution of a paradox, namely when the vertical component of substorms in two German geomagnetic observatories (Wingst and Niemegk) proved to be of opposite sign. This paradox was attributed later to the North German anomaly (Schmucker 1959).

The source of the method is the same as that of all other geoelectromagnetic methods and a similar time series analysis is needed to separate the variations of different periods (frequencies) for single station and array measurements too. Array and single site transfer functions are applied.

Array Transfer Function

The normal field is that which would exist in the presence of one-dimensional layered structure in which the inhomogeneity is embedded. The anomalous field is then most simply defined as the total measured field minus the normal field.

Due to the linearity of the Maxwell field equations, there exists a linear relationship between the anomalous and normal magnetic field components (Schmucker 1970).

$$H_{xa} = T_{xx}H_{xn} + T_{xy}H_{yn} + T_{xz}H_{zn} + \epsilon_x$$

$$H_{ya} = T_{yx}H_{xn} + T_{yy}H_{yn} + T_{yz}H_{zn} + \epsilon_y$$

$$H_{za} = T_{zx}H_{xn} + T_{zy}H_{yn} + T_{zz}H_{zn} + \epsilon_z$$

where H_x , H_y , and H_z are the field components and ϵ is the error of the relation. All these T quantities are period dependent and complex. Subscript “a” and “n” refer to anomalous and normal parts, respectively. The assumption that the source field is uniform, allows the normal part of the H_z component to be taken as zero. Accordingly, the third term on the right-hand side of equations can be neglected.

Single site transfer function With the following condition

$$H_{zn} \ll H_{za}, H_{xa} \ll H_{xn}, H_{ya} \ll H_{yn}$$

the relation between the vertical and horizontal components is

$$H_{za} = T_{zx}H_x + T_{zy}H_y,$$

where T_{zx} and T_{zy} are complex values.

Induction vectors (arrows) are computed separately from the real and imaginary parts of the T values. In practice two variants are used (Wiese 1965; Parkinson 1959). The vector lengths in both cases are the same:

$$L_r = \sqrt{(\text{Re } T_{zx})^2 + (\text{Re } T_{zy})^2},$$

$$L_i = \sqrt{(\text{Im } T_{zx})^2 + (\text{Im } T_{zy})^2}.$$

The azimuth of the Wiese vector (arrow)

$$\phi_w = \tan^{-1} \left(\frac{T_{zy}}{T_{zx}} \right)$$

gives the direction of the maximum correlation between the upward vertical and horizontal field component. This definition of the azimuth implies that the x-axis is directed northwards. The magnitude (length) represents the ratio of vertical field amplitude to the amplitude of the horizontal component with which it correlates (Arora 1997). The Wiese vectors point away from areas of higher conductivity. Conversely, the azimuth of the Parkinson arrow points towards the high electrical conductivity region. The

Geoelectromagnetism,

Fig. 2 Wiese induction vectors measured along the Carpathian conductivity anomaly. (Modified after Jankowski et al. 2005)

induction arrows when displayed on the map clearly identify the location and trend of subsurface conductivity anomalies (Arora 1997).

The MVP (induction vector) has an extended literature. Rokityansky (1982) provided a series of model studies. Arora (1997) published several alternative approximations, which might better determine the structure of the conductive bodies, for example, “perturbation arrows,” “hypothetical event analysis,” Z/H “pseudosection,” and 2D modeling.

Among the field studies conducted in East-Central Europe in which induction vectors were plotted, it is the Carpathian conductivity anomaly (indicated at first by Wiese 1965) that has received the greatest attention, attracting scientists from all neighboring countries. The distribution of the induction vectors is shown in Fig. 2 (after Jankowski et al. 2005) and one of the best models is shown in Fig. 3 (Zhdanov et al. 1986). For the assumed conductive region between 10 and 20 km there are two alternative hypotheses: (a) porous rocks saturated by mineralized water (ionic conduction), (b) conducting rock complex connected to graphite.

At present the induction vectors form an integral part of routine MT interpretation software (e.g., WinGlink) and the vertical magnetic components are also incorporated in MT inversion.

Magnetotelluric Soundings

Basic Formulas

Magnetotellurics (MT) means a joint measurement of the natural electric and magnetic field variations on the surface. Its energy source is partly the same as that of MVS and MVP. Namely, at frequencies $f < 5$ Hz the electromagnetic

(EM) source field is generated by ionospheric as well as magnetospheric phenomena (micropulsations, substorms, etc.) and at frequencies $f > 5$ Hz the EM field is due to worldwide lightning. The source field penetrates into the Earth, where it is reflected from all resistivity interfaces. The measured field is the sum of the primary (source) and secondary (subsurface-dependent) fields. The signal propagation in the subsurface is diffusive. *Skin depth* δ is the depth at which a uniform field is attenuated to $1/e$ of its surface amplitude in a conductor of uniform conductivity:

$$\delta = \sqrt{2/\mu\sigma\omega},$$

where σ is the conductivity (Sm^{-1}), μ is the magnetic permeability (Hm^{-1}), and $\omega \equiv 2\pi f$ is the angular frequency with f denoting the frequency (Hz). The free-space value of magnetic permeability ($\mu = \mu_0 = 4\pi \times 10^{-7} \text{Hm}^{-1}$) is generally assumed. As shown in the above equation, the lower the frequency is, the larger is the magnetotelluric depth of investigation.

The time variations of the two horizontal (E_x and E_y) components of the electric (or telluric) field are measured by using non-polarizable electrodes in a broad period range. The H_x and H_y horizontal geomagnetic field components are measured either with induction coils or fluxgates. From the time series of the horizontal electric and magnetic field components their frequency spectra are determined. In the simplest case, from $E_x(\omega)$ and $H_y(\omega)$ a complex impedance $Z(\omega)$ is computed as follows:

$$Z_{xy}(\omega) = \frac{E_x(\omega)}{H_y(\omega)}.$$

Goelectromagnetism,

Fig. 3 Goelectric and geothermal model of the Carpathian conductivity anomaly and the deepening asthenosphere toward the East European Platform along a NE–SW profile (so-called KAPG geotraverse II) crossing the Transcarpathian region in Ukraine. (After Zhdanov et al. 1986). 1, goelectric boundaries and resistivity values of blocks in Ωm ; 2, deep faults; 3, isotherms; 4, conducting asthenosphere

From Z the apparent resistivity ρ (i.e., the electrical resistivity of a fictitious homogeneous half-space) is defined as

$$\rho = \frac{1}{\omega\mu} |Z_{xy}|^2.$$

The phase difference between the electric and geomagnetic components is given as

$$\varphi = \arg Z_{xy} = \tan^{-1} \frac{\text{Im} Z_{xy}}{\text{Re} Z_{xy}}.$$

In the general case, the impedance is a period-dependent tensor:

$$\begin{pmatrix} E_x \\ E_y \end{pmatrix} = \begin{pmatrix} Z_{xx} & Z_{xy} \\ Z_{yx} & Z_{yy} \end{pmatrix} \begin{pmatrix} H_x \\ H_y \end{pmatrix}$$

where Z_{xy} and Z_{yx} are the antidiagonal or main impedance elements and Z_{xx} and Z_{yy} are the diagonal or additional elements.

For a 1D model (where the goelectric structure varies exclusively with depth), the impedance elements are, theoretically, in the following relationships:

$$Z_{xy} = -Z_{yx} \text{ and } Z_{xx} = Z_{yy} = 0.$$

For a 2D model (where the resistivity section does not change in one of the horizontal direction named by strike direction), the apparent resistivity calculated from E_x and H_y components will differ from that derived from E_y and H_x , that is,

$$Z_{xy} \neq Z_{yx}$$

Furthermore, $Z_{xx} = Z_{yy} = 0$ is valid exclusively when the horizontal axes are aligned along and perpendicular to the strike direction.

One of the basic modes is called as *TE mode* (or *E-polarization*), where the electric field exists only in *strike direction*. The other basic mode is called as *TM mode* (or *H- or B-polarization*), where it is the magnetic field, which has one single component parallel to the strike direction. In the TE mode, there is also a measurable vertical magnetic component (H_z), which is usually also measured; in the TM mode, there is a measurable vertical electric component (which is not measured). The TE and TM mode apparent resistivities represent the goelectric structure in two different ways. The TE mode is more sensitive to deep

Geoelectromagnetism, Fig. 4 Magnetotelluric sounding curves for a layer (ID) model with $R_{h1} = 4 \Omega\text{m}$, h_1 (thickness) = 3 km, $R_{h2} = 2,000 \Omega\text{m}$. According to the Occam and few-layer inversions

the “S-interval” starts at a period of 10 s. At longer periods the telluric (Earth currents) method can be used to determine the thickness of the low resistivity sedimentary layer on a more resistive basement

conductive anomalies, while the TM mode – due to the charge accumulation at the resistivity boundaries – is more sensitive to the inhomogeneity boundaries.

When the model is 3D, the complete impedance tensor has four nonzero complex elements.

MT sounding curves are obtained by plotting apparent resistivity and impedance phase as functions of period (or square root of the period) over a wide period range. In Fig. 4, a 2 layer 1D resistivity model is shown. Note that the resistivity curve is fully logarithmic while the phase curve is semi-logarithmic. $Z_{xy}(\omega)$ and $Z_{yx}(\omega)$ serve as the basis of the TE and TM mode $\rho(\omega)$ and $\varphi(\omega)$ sounding curves. Computing the impedance elements in rotated coordinate systems, one obtains so-called polar diagrams, which characterize the anisotropy of the resistivity distribution.

Interpretation

Complex impedance elements recorded over a range of periods and at many sites along a profile or over an area, can be used to estimate the true resistivity distribution of the subsurface. This procedure is called inversion. Before carrying out inversion, the impedance elements should be corrected from distortions of both technical and structural origin. The “remote reference” method – using the data of simultaneous measuring sites in the

processing – reduces, for example, the effect of man-made electromagnetic noises (Gamble et al. 1979). Different *decomposition* techniques (e.g., (Larsen 1977; Groom and Bailey 1989; Bahr 1991); corrected by Prácser and Szarka 1999; Caldwell et al. 2004) enable suppression of the effect of a near-surface small 3D inhomogeneity causing the “static shift” of galvanic origin. At the same time they inform how well the impedance data correspond to a 2D resistivity model, and give an estimate for the strike direction, too. The papers by Bibby et al. (2005) and by Weaver et al. (2006) also explore the role of the phase tensor in determining dimensionality and strike direction. Due to the fact that the inversion is inherently nonunique, additional geophysical and geological information is needed in order to get a realistic model of the subsurface. The most frequently used 2D inversion algorithms in magnetotellurics are those by Rodi and Mackie (2001) and Siripunvaraporn and Egbert (2000) (see Fig. 7). The fitness of the modeled and measured data is characterized by the root-mean-square (rms) values. Various EM imaging procedures, exploiting the whole information content of the impedance tensor, may also be useful, as proposed by Szarka et al. (2005) and Weaver et al. (2000). For this purpose, Szarka and Menvielle (1997) recommended the system of independent rotational invariants of the impedance tensor. The usefulness

of this approach was demonstrated in detail by Novák (2009) using field data. In recent years, many papers have been published on 3D modeling and inversion and some have been presented at the biennial International Association of Geomagnetism and Aeronomy (IAGA) Workshops on Electromagnetic Induction in the Earth, including reviews of these topics, e.g., Avdeev (2005).

Application to Geosciences and Future Directions

MVS, MVP, MT, and to a lesser extent tellurics have received a very wide application in studying the structure and physical processes of the Earth at various local, regional, and global scales. The development of field applications has been disseminated at the biennial IAGA electromagnetic induction workshops since 1972 (see MTNet website, http://www.dias.ie/mtnet/workinggroup/wg_wsreviews.html) and at assemblies of IAGA. For example, at the last (11th) IAGA Assembly (Sopron, 23–30 August 2009, www.iaga2009sopron.hu), a wide spectrum of geoelectromagnetic studies, from the surface to the middle of mantle, was presented: theoretical and practical aspects of near-surface and environmental problems, oceanic geophysical exploration, formation and deformation of the continental lithosphere, crustal

tectonic processes, deep mantle structure, and data interpretation methods.

In order to illustrate the wealth of geoelectromagnetic applications, the authors present a selection from their own results from the Pannonian Basin, which is a very complex geological-geophysical unit of the Carpatho-Pannonian region. Such a summary cannot be done without mentioning other geoelectromagnetic investigations of the most well-known global geodynamic phenomena, such as the active plate tectonics in the Himalayas, Andes, San Andreas Fault, Afar region, etc. Earth being a “dynamic planet,” great efforts have also been devoted to mitigate the geohazards: earthquakes, volcanoes (as accompanying phenomena of the plate tectonics), and landslides (Bedrosian 2007; Korja 2007).

Before discussing the electrical conductivity anomalies/structures in the Pannonian Basin, we give a short description about its geology from those aspects that constrain the spatial distribution of electrical resistivity in the subsurface. The Pannonian Basin has a fairly thick and relatively uniform low electrical resistivity sedimentary cover of Late Tertiary origin, which was investigated in detail by telluric/magnetotelluric soundings. According to Haas (2001), the Pre-Neogene basement “shows a mosaic pattern of heterogeneous structural elements, a collage of allochthonous terrains derived from different parts of the Tethyan realm” (Fig. 5).

Goelectromagnetism, Fig. 5 Pre-Tertiary structural units of Hungary and depth of the pre-tertiary basement (Haas 2001)

In the basement there are two large Mega-units of composite terrains, which are separated by the ENE-WSW trending Mid-Hungarian Lineament. The South-Pannonian Mega-unit is the so-called TISIA (TISZA) Terrain and the North-Pannonian one is the so-called ALCAPA Mega-unit, which was formed from different smaller terrains. One of them is the PELSO in its southern part.

The evolution of the Pannonian Basin is significantly determined by the Miocene synrift, accompanied with a strong thermal heating, and leading to appraisal of crustal and mantle horizons and an extension of the basin by 10–30%, pre-dominantly in the NE–SW direction (Horváth and Berckhemer 1982). These features are extremely dominant in the deep extensional sedimentary sub-basins (e.g., in the Békés basin).

The spatial distribution of electrical resistivity/conductivity is influenced in the Pannonian Basin by the position, boundaries, and mosaic structure of the Megaunits and tectonic and thermal effects in the lithosphere, caused by synrift extension that has only been slowly compensated by the presently ongoing compression of the basin. The conductivity structures conserve the history of basin. Due to upheating of the Pannonian Basin – indicated by the high heat flow values at the surface of about 100 mW/m² – two geoelectric conductors are in an elevated position, in comparison to the surrounding mainly outer Carpathian: Paleozoic and Proterozoic regions.

Application of geoelectromagnetic methods is illustrated in five snapshots, representing various depth ranges: asthenosphere, mega-blocks, middle crust, upper crust, and near-surface.

1. *Asthenosphere.* The depth of the high-conductivity asthenosphere – in which the temperature approximates the solidus of the mantle peridotite, so that a partial melting can start – is in the Pannonian Basin at about 60 km depth, indicated by Ádám (1965). In platforms and shield areas the asthenosphere is at much deeper position – if it exists at all. Its estimated value is about 250 km as concluded by extended projects such as BEAR in Finland (Korja and BEAR Working Group 2003) and CEMES (Yu Semenov et al. 2008) in East-Central Europe (See also Fig. 3). The MT indications of the conductive asthenosphere at an elevated position within Pannonian Basin were confirmed with reflection seismics (Posgay 1975) and also with a thermobarographic diagram of well-equilibrated peridotite xenolith from the PELSO (Embey-Isztin et al. 2001). The elevated position is in close correlation with enhanced heat flow values (Fig. 6a, Ádám 1978). Its smallest depth of about 50 km was observed in the Békés extensional sub-basin (Ádám et al. 1996). The map of asthenospheric depth in and around the Pannonian Basin is shown by Fig. 6b as the result of seismic, seismological, and magnetotelluric measurements (See in Horvath et al. 2006, based partly on the MT data of Ádám and Wessztergom 2001).
2. *Middle crust.* In the middle crust the transition between the brittle and ductile zone is also temperature dependent, which might be due to dehydration as proposed by Hyndman and Shearer (1989). Ádám (1978, 1987) found a relation between the mid-crustal conductivity increase and the regional heat flow values. In the Pannonian Basin there is only a weak indication of this anomaly at a depth of about 15–17 km, but this is supported by the lower limit of seismic focal depths and by strength decrease. The electrical conductivity of the lower crust was reviewed by Jones (1992).
3. *Boundaries of mega-units.* The boundaries of the Mega-units and their mosaics in the Pannonian Basin were studied among others along the deep seismic CEL-07 profile in SW Hungary with 72 deep MTS. The distance between neighboring magnetotelluric stations was in average only 2 km. The CEL-07 profile is shown together with the complicated basement tectonic structure in Fig. 5.

The resistivity profile of the TE mode inversion along CEL-07 is shown in Fig. 7 (the TM mode inversion profile is strongly distorted by charge accumulation at the boundary of electrical inhomogeneities falsifying the values of the resistivity distribution). The TE mode inversion clearly expresses the conductivity anomalies at the boundaries of the Mega-units: the Balaton + Balatonfő double lineaments at the southern border of the PELSO M.u. (mosaic of the ALCAPA M.u.) and the Mid-Hungarian Line at the northern border of TISIA M.u. The horizontal electric conductance of the lineaments is about 2,500–3,000 S, starting at a depth of about 7 km. The source of the conductivity anomaly is certainly hot saline fluid containing also SiO₂ solution. Deep borehole data refer to accumulation of CO₂, increase of He concentration, etc. in the deep fractures. A high value of convective heat transfer, especially in volcanic eruption centers, also increases the electrical conductivity in these tectonic zones, which (e.g., the Balaton Line) is also indicated by the zero value of the induction vectors (Ádám et al. 2005).

4. *Crustal conductivity anomalies.* On the northern part of the CEL-07 resistivity profile there appears another conductivity anomaly that is assumed to be the continuation or ending of one of the extreme high fracture zones related to the Transdanubian Conductivity Anomaly (TCA) studied by 300 deep MT soundings (Ádám 2001). The TCA consists of a conductive layer at about 5 km depth and of three significant fracture zones in the NE–SW direction. Their horizontal electric conductance value can reach 10,000 S. Such high conductance values make it probable that the sources of the anomaly are graphite/graphitic shists as well as fluid, which are partly within, and partly under the thick Mesozoic limestone sequence of the Bakony Mts. In this

Geoelectromagnetism, Fig. 6 (a) Relation between the depth of the conductive asthenosphere and the regional heat flow (Ádám 1978), (b) The map of the asthenospheric depth in and around the Pannonian Basin

as results of seismic/seismological/magnetotelluric results (Horvath et al. 2006; Ádám and Wetztergom 2001)

area there is significant seismic attenuation (Zsíros 1985), and this must be due to an electrical conductor (Glover and Ádám 2008). The large fractures as shown by the strongly reduced induction vectors (Fig. 8) are connected to the hypocenters of the earthquakes (e.g., Mór in, 1809, Berhida in 1985, rarely exceeding a magnitude of 6 on Richter's scale). Glover and Ádám (2008) found a correlation between the depth to the zone of this high electrical

conductivity anomaly and earthquake focal depths. According to Ogawa (2007) the earthquakes occur at the boundaries of the electric conductors, where only aseismic slip or elastic deformation can happen, rather than within the conductors themselves. In this way the energy can be transported towards the brittle zone, causing devastating earthquakes. In the presence of the hypothetical enhancement of magnetic permeability at the Curie depth (Kiss

Geoelectromagnetism, Fig. 7 The resistivity profile of the TE+ Hz nonlinear conjugate gradient inversion of the magnetotelluric measurements along the CEL-07 profile (RMS = 1.344132). See the conductors corresponding to the deep boundary fractures (Ádám et al. 2005)

Geoelectromagnetism, Fig. 8 Wiese induction vectors along the deep fractures of the TCA (Wallner 1977)

et al. 2005), MT interpretation of upper and middle crustal inhomogeneities should be carried out with a special care.

5. *Near-surface*. In order to study the near-surface depth range, either higher frequencies or local sources should be applied. Various high-frequency variants have been developed: instead of the classical MVP the so-called VLF; instead of the classical magnetotellurics: audiomagnetotellurics (AMT), radiomagnetotellurics (RMT), or VLF-EM. If the source is finite, we quickly arrive at various near-surface electromagnetic induction and direct current methods.

As a result of the various EM induction methods becoming increasingly important, the number of geoelectromagnetic papers published in international journals has shown an upward trend. Recently, Bedrosian (2007) reviewed MT measurements, which were carried out in the Himalayas (Lemonnier et al. 1999), in Southern Tibet (Li et al. 2003), in the Andean margin (Brasse et al. 2002), etc. In each of these dynamic areas the electrical conductivity anomalies appear at their most active segments, which has been also indicated by thermal activation (in forms of high heat flow), earthquakes, volcanoes, recent crustal movements, regional metamorphism (e.g., graphitization), partial melting, etc. Korja (2007) gives in his review a comprehensive description about the conductive anomalies in Europe. As Bedrosian (2007) stated, for a correct interpretation of MT (EM) data, due to the nonuniqueness of the geophysical inverse problems, independent geological and geophysical information is necessary. This conclusion is highly confirmed by our experiences with geoelectromagnetic results from the Pannonian Basin.

For further reading on various topics in geoelectromagnetism covered in this entry, both practical and theoretical, the reader is referred to the specialized monographs by Wait (1962), Berdichevsky and Zhdanov (1984), Weaver (1994), Simpson and Bahr (2005), and Zhdanov (2009) among others in sequence of the publication year.

Geoid

Paramesh Banerjee

Earth Observatory of Singapore, Prayukti Geomatics Pte Ltd, Singapore, Singapore

Synonyms

Equipotential surface at mean sea level

Definition

- Geoid** The gravitational equipotential surface of the Earth that best approximates the “mean sea level.”
- Tectonic Forces** Forces originating from within the Earth that alters surface configuration of the Earth through uplift, movement, and deformation of the parts of the Earth's crust.

Introduction

Geoid defines the physical shape of the earth and serves as a globally consistent reference surface for measuring heights. The concept of geoid was introduced by Listing (1873). Like any homogeneous liquid in hydrostatic equilibrium does, ocean water surface also tends to follow a gravity equipotential surface. The equipotential surface that best matches the ocean water surface on a global scale is defined as the geoid. Because of variation in salinity, particle content, water temperature, ocean currents, climate-related sea level rise, tectonic motions, etc., ocean water surface does not conform perfectly to the geoid surface. A best fit surface is thus adopted and maximum deviation of ± 2 m. has been observed globally. The geoid is locally realized as “mean sea level,” by averaging water levels at tide gauge stations. This “mean sea level” is traditionally used as a reference for measuring heights over lands using leveling instruments. In surveying parlance, geoid and “mean sea level” are thus synonymous. Extension of that “sea level” inside continents is done either by leveling traverses or by modeling geoid using gravimetric data.

Geoid and Heights

Heights measured referenced to the geoid is called orthometric height (H) (Fig. 1) and is the most commonly used height in engineering and mapping all over the world. Realization of the geoid surface is not always a straight forward process and requires careful processing of surface gravity data. To overcome problems associated with unknown

subsurface density inhomogeneity that are required in computing geoid from surface gravity measurements, a new concept of “quasi-geoid” was introduced by Molodensky et al. (1960). Some European and former Soviet Union countries use quasi-geoid, instead of geoid, as the reference surface to the height. Quasi-geoid is a superficial surface, and the referenced height is known as “normal height.” With more subsurface and crustal structures being explored using geophysical techniques, the geoid remains most widely used and robust reference surface.

Geoid defines the physical shape of the earth. It is a real surface with irregularities and undulations caused by subsurface density inhomogeneities. A geocentric ellipsoid aligned with the rotational axis of the earth and best fitting the geoid defines the geometric shape of the earth. The reference ellipsoid provides a smooth, mathematically defined surface and has no physical existence. But it serves as the basis of the reference system for defining horizontal coordinates of points on the earth’s surface. Geoid forms the reference for the vertical datum. Vertical separation between the geoid and ellipsoid corresponding to a point on the surface of the earth is known as geoidal height (N), geoid anomaly, or geoid undulation, and varies between $+100$ m and -100 m globally. All positioning measurements made by satellite-based geodetic system, e.g., GNSS (Global Navigation Satellite System), including GPS (Global Positioning System), are referred to the reference ellipsoid. Height of any point referenced to the ellipsoid is called ellipsoidal or geodetic height (h). It has no practical use unless converted to the orthometric height. Relationship between the ellipsoidal (h), orthometric (H), and geoid (N) heights are given by Eq. (1). The relationship is approximate, but precise enough for most of the practical purposes, particularly when used in differential mode.

$$N \approx h - H \quad (1)$$

Because of the recent advances in space geodetic techniques, ellipsoidal heights can be measured with sub-cm level accuracy. Whereas, orthometric height measurements using terrestrial leveling method could attain 10–15 cm level accuracy even at the best measured first-order leveling networks. A geoid model (N) enables to convert high accuracy ellipsoidal heights into orthometric heights using Eq. (1). Determination of a highly accurate geoid model has thus become a prerequisite to derive benefits of space geodetic techniques which is easy, highly accurate, globally consistent, and economic.

Geoid Modeling from Gravity Data

One simple way of estimating geoid height N is measuring a leveling benchmark with GNSS instrument, typically known as

Geoid, Fig. 1 A simplified cartoon showing geoid and spheroid levels both over the continents and oceans. Geoid undulation varies between $+100$ m to -100 m. Indian Ocean has the lowest geoid anomaly

Geoid, Fig. 2 A 3-D visualization of global geoid undulation model from the EIGEN-6C4 combined gravity data. For details, see Ince et al. (2019)

“GPS-on-Leveling” technique, and applying Eq. (1) to get N . Sparse measurements can be interpolated to other points within nearby region where geoid can be assumed to be linear. But the accuracy of the geoid height is limited by terrestrial leveling measurements which is error prone over long distance, expensive, and slow. These problems are more severe in mountainous region, places far away from tide gauge stations, and tectonically active zones. Measurement error can accumulate to the order of meter or more.

Geoid can be modeled from gravity data which are available in plenty and easy to acquire, by surface measurements, airborne surveys, and satellite tracking. Gravity field being the vertical gradient of the gravity potential, integration of the properly reduced gravity anomalies using the classical Stokes Integral (Stokes 1849) leads to the gravity potentials and geoid model. Typically satellite gravity data are used to develop global geoid models. To attain higher resolution at regional scale, both airborne and surface gravity measurements along with high-resolution topographic data are additionally used. With further developments in processing techniques, availability of refined global gravity model like EGM08, high-resolution geopotential models derived from GRACE (Tapley et al. 2004) and GOCE (Rummel 2010) missions, high-resolution Digital Elevation Models (SRTM, ETOPO, Lidar, etc.), and availability of more and more surface and airborne gravity measurements, objectives of developing a national geoid model with 1 cm precision seems more and more achievable. In mountainous regions, dilution of precision to one order of magnitude is expected. Developing a high accuracy, robust, and GNSS-friendly

height system based on a precise geoid model has become a priority in many countries in recent years. A recent high-resolution global geoid model is shown in Fig. 2 (Ince et al. 2019).

Measuring Height of the Everest

Measuring the height of the Mt. Everest, the highest topographic feature of the earth, is an interesting example of use of geoid in recent time. Measuring Mt. Everest has always remained a challenge to the geodesists. Starting with the classic triangulation method in 1855 by India, a series of measurements by China, USA, Europe, and Nepal gradually improved the precision of the measurements. The latest effort initiated by the Survey Department, Nepal, is to use GNSS measurements at the top and use a precise geoid model to get the orthometric height of the peak. In May, 2019, one Nepal Survey Dept. officer scaled the peak with a GNSS receiver and could collect data for around 30 min. A country-wide airborne gravity survey was carried out in Nepal (Forsberg et al. 2011) during 2010 and a precise geoid model was developed by Forsberg et al. (2011) with 7 cm precision. A 3D depiction is shown in Fig. 3. More surface gravity measurements have been recently added to further refine Forsberg’s geoid. The challenge of measuring the height of Mt. Everest has essentially boiled down to the challenge of developing most refined geoid map of the region. Official declaration from the Nepal Survey Dept. of the latest height is being expected soon.

Geoid, Fig. 3 Geoid model of Nepal from airborne gravity data (Forsberg et al. 2011). Starting from the Indian peninsula (−60 m), geoid surface goes up to −20 m in High Himalaya

Geoid Anomaly and Tectonics

Deviation of the actual geoid surface from the reference spheroid is known as geoid anomaly. Figure 4 shows the global geoid height anomaly (Bowin 2000). The largest geoid anomaly is a 100 m deep “hole” south of India, in the Indian Ocean. This huge geoid “low” is caused by a mass deficiency in the mantle underneath the sea. Other short wavelength geoid anomalies exist along the oceanic trenches where one tectonic plate subsides underneath another plate or along the mid-oceanic ridges where hot mantle material swells up to produce new oceanic crust. Geoid anomaly generally has a positive correlation with free-air gravity anomaly. However, gravity anomaly is more sensitive to the shallower features, whereas geoid anomaly is more sensitive to the deeper mass inhomogeneity.

Study of the geoid anomaly helps to understand the distribution of large scale density inhomogeneity, the state of isostatic compensation, and also about the flexural property of the lithosphere. Global geoid anomaly data indicates that, when loaded (or unloaded) with a large dimension surface load (e.g., a mountain formation or glaciation–deglaciation process) during a prolonged period, mantle flows and adjusts and the surface load eventually attains hydrostatic equilibrium. In contrast, short-period or small-scale surface load is not isostatically compensated. These are explained by a visco-elastic lithosphere which is strong enough to support at a smaller spatial and temporal scale, but has a finite viscosity and flows like a fluid at a larger spatial and temporal domain. Study of spatial as well as temporal variation of the geoid anomaly can thus be a very useful tool to understand mechanical properties of the lithosphere. It may be noted that isostatically balanced mass distribution does not cause zero geoid anomaly. An isostatically compensated mountain range of 3 km height causes a positive geoid anomaly of ~16 m, where a 5-km deep ocean basin would result a negative geoid anomaly of about 9 m (Fowler 1996). As seen in

Fig. 3, Himalayan topography of around 6000 m average height caused a geoid anomaly of around 35 m (relative to stable India). As geoid anomaly is more sensitive to lateral variation in lithospheric density structure, surface measurements of geoid anomaly can provide a very useful tool to study subcrustal configuration across a plate boundary (Banerjee et al. 1999).

GRACE and Coseismic Deformation

GRACE (Gravity Recovery and Climate Experiment) twin satellite system has made it possible to measure temporal variation of geoid height at a global scale with an accuracy of 2–3 mm (Tapley et al. 2004). The 2004 Sumatra Andaman earthquake (Mw 9.2) provided an opportunity to measure coseismic as well as post-seismic gravity and mass variations using GRACE data (Han et al. 2006; Chen et al. 2007). Sudden change in lithospheric density structure as well as vertical movement could be detected in GRACE data (Fig. 5). With this leap in space geodesy, remote sensing of earth’s geoid provides another important tool to study tectonic processes.

Tectonic Forces

Tectonic forces acting on a lithospheric plate results in plate motion as well as accumulation of stresses, both in vertical and horizontal directions. Surface deformation and earthquakes are direct consequences of these stresses. Origin of the tectonic forces mostly lie in the flow in the asthenosphere which may either drive or resist the motion of the overlying plate. In the subduction zone, gravitational pull of the down going slab (slab pull) plays a more important role in driving the plate motion than the “ridge pushes” where slabs are driven away from the mid-oceanic ridges. Plate motion also creates traction on the base of the overlying continents

Geoid, Fig. 5 A change in crust-mantle mass distribution caused by 2004 Sumatra-Andaman earthquake as detected by GRACE gravity mission (Chen et al. 2007)

Geoid, Fig. 6 Different tectonic forces in play in a subduction zone where the subsiding slab sinks in weaker asthenosphere (slab pull), which excites mantle flow, thus creating a traction at the base of the plate (shown by small grey arrows at the base of the plate). Continental crust and oceanic crust are shown in light grey and black respectively, whereas mantle lithosphere is in dark grey

(Humphreys and Coblenz 2007). Another important source of force is generated by the lateral variation in density and thickness in the lithosphere which generates a gradient in gravitational potential energy (GPE). Figure 6 illustrates

how a subducting slab generates GPE gradient and basal traction force. Tibetan plateau is an example of high GPE where continental collision produced high topography, thickened crust, extensional stresses on the plateau, and compression at the edges.

Geoid height variations are linearly proportional to the GPE gradients in an isostatically balanced lithosphere (Turcotte and Schubert 2002). Geoid gradients can thus be used to study lithospheric stress gradients. Lithosphere-scale density inhomogeneities are reflected in shorter wavelength geoid anomalies. This, in combination with integrated density moment computed using a crustal density model at longer wavelength, can be used to produce GPE (Humphreys and Coblentz 2007).

Geoid Determination, Computational Methods

Michael G. Sideris

Department of Geomatics Engineering, University of Calgary, Calgary, AB, Canada

Definition

<i>The geoid</i>	is the equipotential surface of the Earth's gravity field, which best approximates the mean sea level at rest.
<i>Geoid determination</i>	encompasses the methodology and computational techniques used to calculate the values of the geoid undulations in particular points or regions.

Introduction

In this entry, we are presenting numerical methods for estimating geoid undulations and other relevant quantities, based on the theory presented in the article ► “[Geoid Determination, Theory and Principles](#)”. We will refer to formulas in that article by the equation number followed by Sideris and then by ► “[Geoid Determination, Theory and Principles](#)”. For example, Stokes's equation will be referred to as Eq. 17 in Sideris, ► “[Geoid Determination, Theory and Principles](#)”.

The Remove-Compute-Restore Technique

In practice, we can evaluate Stokes's equation by numerical integration using only discrete data; therefore, short-wavelength information will not be properly represented in the solution (it will be aliased). In addition, we use data only in a certain region, and therefore the long-wavelength contributions of the gravity field will not be present in the results and must be computed in another way. These problems can be remedied by using a global geopotential model (GM) and heights, H , in a digital elevation model (DEM) to obtain the long and short wavelengths of the field, respectively. This leads to the standard *remove-compute-restore technique*, in which the long and short wavelengths are first removed from the gravity anomalies in a preprocessing step, then the residual anomalies Δg_r are used to compute residual undulations $N_{\Delta g_r}$, and then the long- and short-wavelength contributions are restored in a post-processing step. The computation is based on the following formula:

Geoid Determination, Computational Methods, Fig. 1 Contributions of different data to regional geoid determination

$$N = N_{GM} + N_{\Delta g_r} + N_H, \Delta g_r = \Delta g - \Delta g_{GM} - \Delta g_H \quad (1)$$

where Δg_H denotes the terrain contribution and N_H the corresponding indirect effect on the geoid; see Fig. 1. It should also be noted that such residual anomalies are typically smaller and smoother and therefore appropriate for use in interpolation and in the creation of gridded values by, e.g., least-squares collocation.

Computation of the GM-Contributions

The geopotential model parts of Δg and N are usually computed by the spherical approximation of Eqs. 15 and 16 in Sideris, ▶ “Geoid Determination, Theory and Principles” from the coefficients of a GM of maximum degree $n_{\max}$, which is a function of the resolution of the data that were used to compute the coefficients C_{nm} , S_{nm} :

$$N_{GM_P} = R \sum_{n=2}^{n_{\max}} \sum_{m=0}^n [C_{nm} \cos(m\lambda_P) + S_{nm} \sin(m\lambda_P)] P_{nm}(\sin \phi_P) \quad (2)$$

$$\Delta g_{GM_P} = G \sum_{n=2}^{n_{\max}} (n-1) \sum_{m=0}^n [C_{nm} \cos(m\lambda_P) + S_{nm} \sin(m\lambda_P)] P_{nm}(\sin \phi_P) \quad (3)$$

G and R are the mean gravity and mean radius of the sphere, and ϕ_P , λ_P are the spherical latitude and longitude of the computation point. This representation causes an omission or truncation error, but there is also a commission error because the data used to estimate the coefficients, and therefore also the coefficients themselves, do contain errors. Naturally, the spherical approximation itself causes an additional error, and therefore Eqs. 15 and 16 in Sideris, ▶ “Geoid Determination, Theory and Principles” are preferable to Eqs. 2 and 3.

A comprehensive discussion on the determination and proper use of GM coefficients can be found in ▶ “Spherical Harmonic Analysis Applied to Potential Fields”, in

▶ “Gravity, Global Models”, and in Chapter 6 in Sansò and Sideris (2013). Information on the high-resolution EGM08 model is given in Pavlis et al. (2012), and a complete set of freely available GMs is provided by the ICGEM (International Centre for Global Earth Models) Service of the International Association of Geodesy at <http://icgem.gfz-potsdam.de/home>.

Computation of the Δg -Contribution

The contribution of gravity anomalies can be computed by use of either Stokes’s integral or least-squares collocation (LSC). For simplicity in the notation, we will often write just N and Δg instead of $N_{\Delta g_r}$ and Δg_r in the equations, respectively.

Evaluation of Stokes’s integral. Stokes’s integral can be evaluated either on the sphere or on the plane by numerical integration using data on circular sectors (ring integration method) or on regular grids. Since gravity data are typically available on grids, and because Stokes’s integral is a convolution integral on the plane and along parallels on the sphere, we will discuss here the integral’s evaluation on regular grids by use of the very efficient *fast Fourier transform* (FFT) *technique* (Bracewell 2000).

On the sphere, using Eqs. 17, 18, and 19 in Sideris, ▶ “Geoid Determination, Theory and Principles”, we can write Stokes’s integral explicitly as

$$N_P = \frac{R}{4\pi\gamma} \iint_{\sigma} \Delta g S(\phi_P, \phi, \lambda - \lambda_P) \cos \phi d\phi d\lambda \quad (4)$$

which is a convolution between $\Delta g \cos \phi$ and the Stokes kernel S only along parallels. For Δg_r given on $M \times N$ points on a spherical grid with spacings $\Delta \phi$, $\Delta \lambda$, Eq. 4 can be written for every parallel of constant latitude ϕ_l as

$$\begin{aligned} N_{\Delta g_r}(\phi_l, \lambda_k) &= \frac{R}{4\pi\gamma} \sum_{j=0}^{N-1} \left[\sum_{i=0}^{M-1} \Delta g_r(\phi_j, \lambda_i) \cos \phi_j S(\phi_l, \phi_j, \lambda_k - \lambda_i) \Delta \lambda \right] \Delta \phi \\ &= \frac{R}{4\pi\gamma} \sum_{j=0}^{N-1} \left[(\Delta g_r(\phi_j, \lambda_k) \cos \phi_j) * S(\phi_l, \phi_j, \lambda_k) \right] \Delta \phi, \\ \phi_l &= \phi_1, \phi_2, \dots, \phi_N \end{aligned} \quad (5)$$

The brackets in Eq. 5 contain a one-dimensional (1D) discrete convolution with respect to λ , i.e., along a parallel. Therefore, the above discrete convolution, denoted by $*$, can be evaluated by the 1D FFT (Strang van Hees 1990; Haagmans et al. 1993) as follows:

$$N_{\Delta g_r}(\phi_l, \lambda_k) = \frac{R}{4\pi\gamma} F_\lambda^{-1} \left\{ \sum_{j=0}^{N-1} F_\lambda \left\{ \Delta g_r(\phi_j, \lambda_k) \cos \phi_j \right\} \right. \\ \left. F_\lambda \left\{ S(\phi_l, \phi_j, \lambda_k) \right\} \right\} \Delta \phi, \\ \phi_l = \phi_1, \phi_2, \dots, \phi_N \quad (6)$$

where F_λ denotes the 1D direct Fourier transform and F_λ^{-1} the 1D inverse Fourier transform along parallels of constant latitude (Sideris 2016). Although Eq. 6 is rigorous, its evaluation is not as efficient as it could be, as it still requires numerical summation along meridians. By employing various approximations for the Stokes kernel function, such as, e.g., $\cos \phi_P \cos \phi = \cos^2 \bar{\phi}$, where $\bar{\phi}$ is the mean latitude of the computation area, it is possible to transform Eq. 6 into a two-dimensional (2D) convolution. In this case, accuracy is traded for efficiency. Detailed formulas can be found in Forsberg and Sideris (1993).

In planar approximation, which can be employed when the data is available in a limited area E with extent of no more than several degrees in each direction, the Stokes kernel can be approximated by its first term $1/\sin(\psi/2)$. Then the kernel and the differential area can be converted to their planar equivalents, i.e., $S(\psi) \approx 1/\sin(\psi/2) \approx 2/\psi \approx 2R/l$, and $Rd\sigma = dx dy$, yielding the following *planar form of Stokes's integral* (Schwarz et al. 1990; Sideris 2016):

$$N_P = \frac{1}{2\pi\gamma} \iint_E \frac{\Delta g}{l} dx dy = \frac{1}{2\pi\gamma} \Delta g_P * l_{N_P} \quad (7)$$

where l is the planar distance between data and computation point and l_N is the planar form of Stokes's kernel:

$$l_N = (x^2 + y^2)^{-1/2} \quad (8)$$

On a grid with spacings $\Delta x, \Delta y$, the above 2D convolution integral takes the discrete form

$$N_{\Delta g_r}(x_k, y_l) = \frac{1}{2\pi\gamma} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} \Delta g_r(x_i, y_j) l_N(x_k - x_i, y_l - y_j) \\ \Delta x \Delta y = \frac{1}{2\pi\gamma} \Delta g_r(x_k, y_l) * l_N(x_k, y_l) \quad (9)$$

$$l_N(x_k - x_i, y_l - y_j) = \begin{cases} \left[(x_k - x_i)^2 + (y_l - y_j)^2 \right]^{-1/2}, & x_k \neq x_i \text{ or } y_l \neq y_j \\ 0, & x_k = x_i \text{ and } y_l = y_j \end{cases} \quad (10)$$

Geoid undulations can then be evaluated by the 2D FFT as follows (Sideris 2016):

$$N_{\Delta g_r}(x_k, y_l) = \frac{1}{2\pi\gamma} F^{-1} \{ F \{ \Delta g_r(x_k, y_l) \} F \{ l_N(x_k, y_l) \} \} \quad (11a)$$

or, in more compact form (which we will use for all convolutions from this point on)

$$N_P = \frac{1}{2\pi\gamma} F^{-1} \{ F \{ \Delta g_P \} F \{ l_{N_P} \} \} \quad (11b)$$

Because $S(\psi)$ and l_N are singular at the origin, the contribution of the gravity anomaly of the computation point must be evaluated separately and added to the results of the convolutions. On the sphere, Hofmann-Wellenof and Moritz (2006) give this contribution approximately as

$$dN_{\Delta g_r}(\phi_P, \lambda_P) \approx \gamma^{-1} s_o \Delta g_r(\phi_P, \lambda_P) \quad (12)$$

where s_o denotes the radius of a small area around the computation point in which Δg_r can be considered constant. On the plane, the corresponding equation would be

$$dN_{\Delta g_r}(x_P, y_P) \approx \gamma^{-1} \sqrt{\frac{\Delta x \Delta y}{\pi}} \Delta g_r(x_P, y_P) \quad (13)$$

Equation 11 employs the numerical evaluation of the spectrum of Stokes's kernel and is the one that should be used in practice (with proper zero padding of the data) if we want the results from FFT to be identical to those from numerical integration; see Li and Sideris (1993). This is in fact true for any of the other convolution integrals that we are discussing here. Nevertheless, it is well-known from Fourier theory that the inverse distance function l_N has an analytical spectrum, which is the inverse frequency q^{-1} in the frequency domain. Using u, v, w to denote the frequencies corresponding to x, y, z , this spectrum is

$$F \{ l_N(x, y) \} = F \left\{ (x^2 + y^2)^{-1/2} \right\} = (u^2 + v^2)^{-1/2} = q^{-1} \quad (14)$$

and therefore Eq. 7 can be evaluated as follows:

$$N_P = \frac{1}{2\pi\gamma} F^{-1} \{ F \{ \Delta g_P \} q^{-1} \} \quad (15)$$

This representation clearly shows that Stokes's integral is a smoothing, mainly low-frequency-dependent operator, and therefore geoid undulations are more sensitive to the long wavelengths of the gravity field.

The FFT method can use either mean or point data on a grid and computes simultaneously the geoidal heights at all grid points; see Sideris and Tziavos (1988) for the formulas with mean data. A large area can thus be covered very fast and with minimum cost. An interpolation technique such as LSC must be employed for predicting geoidal heights at points not on the grid and/or to grid irregular gravity anomalies. With gridded data, the FFT technique is by far the fastest of all available methods. Criticism that only the FFT suffers from leakage and aliasing effects are not valid since these effects depend on data density and coverage and thus affect all methods.

Given gridded gravity and topography data, the Molodensky solution of Eqs. 20, 21, and 22 in Sideris, ► “Geoid Determination, Theory and Principles” can also be efficiently evaluated by FFT. Details can be found in Sideris (1987) and Schwarz et al. (1990).

Computation by least-squares collocation. A solution can also be obtained using least-squares collocation (LSC). For example, in the simple case that we only want to predict residual geoid undulations from residual gravity anomalies, Eqs. 26 and 27 in Sideris, ► “Geoid Determination, Theory and Principles” reduce to

$$\hat{N}_{Ag} = \mathbf{C}_{N\Delta g} (\mathbf{C}_{\Delta g\Delta g} + \mathbf{C}_{nn})^{-1} \Delta \mathbf{g} \quad (16)$$

$$\mathbf{C}_{ee} = \mathbf{C}_{NN} - \mathbf{C}_{N\Delta g} (\mathbf{C}_{\Delta g\Delta g} + \mathbf{C}_{nn})^{-1} \mathbf{C}_{\Delta gN} \quad (17)$$

Given the covariance matrix for T , $\mathbf{C}_{TT}$, the other covariance matrices can be derived by covariance propagation using Eqs. 12 and 13 in Sideris, ► “Geoid Determination, Theory and Principles” as follows:

$$\begin{aligned} \mathbf{C}_{NN} &= \frac{1}{\gamma^2} \mathbf{C}_{TT}, \\ \mathbf{C}_{N\Delta g} &= \frac{1}{\gamma} \left(-\frac{\partial \mathbf{C}_{TT}}{\partial h} + \frac{1}{\gamma} \frac{\partial \gamma}{\partial h} \mathbf{C}_{TT} \right), \\ \mathbf{C}_{\Delta g\Delta g} &= \left(-\frac{\partial}{\partial h} + \frac{1}{\gamma} \frac{\partial \gamma}{\partial h} \right) \left(-\frac{\partial \mathbf{C}_{TT}}{\partial h} + \frac{1}{\gamma} \frac{\partial \gamma}{\partial h} \mathbf{C}_{TT} \right) \end{aligned} \quad (18)$$

LSC’s drawback is the need for inverting large covariance matrices or simply solving large systems of linear equations, which in practice often prevents the utilization of all given data, and thus prevents the application of LSC over large regions. To circumvent this problem, if gridded data are available, LSC can be applied in the frequency domain. This is actually related directly to the use of FFT formulas with noisy, heterogeneous data. It will in fact be shown below that the FFT method can use heterogeneous data, provided that they are given on a grid, and can produce error estimates, provided that the power spectral density (PSD) functions, which are the Fourier transform of the covariance functions, of the data and their noise are known. In this case, the

technique is equivalent to frequency-domain collocation; see also Sideris (2016).

Computation by frequency-domain collocation. To illustrate how error propagation can be used with Stokes’s integral, we assume that the anomalies have errors n with known PSD P_{nn} . In this case, Stokes’s convolution of, e.g., Eq. 7 becomes

$$N = (\Delta g + n) * s + e \quad (19)$$

where $s = l_N/(2\pi\gamma)$ and e is the error of the estimated undulations.

Making use of the definition of the PSD function P_{fg} for two signals f and g (Bendat and Piersol 2010) as

$$P_{fg} = F\{f\}F\{g\}^* \quad (20)$$

where the superscript $*$ denotes complex conjugate, and assuming no correlation between the signal and noise, the PSD of N and the cross-PSD of Δg and N can be derived as follows (Sideris 2016):

$$P_{NN} = P_{ee} + S(P_{\Delta g\Delta g} + P_{nn})S^* \quad (21)$$

$$P_{\Delta gN} = P_{ee} + S(P_{\Delta g\Delta g} + P_{nn}) \quad (22)$$

where $S = F\{s\}$ and $P_{\Delta g\Delta g}$ is the PSD of the gravity anomalies. From the above equations, the spectrum of Stokes’s kernel and the output-noise PSD can be obtained as

$$S = \frac{P_{N\Delta g}}{P_{\Delta g\Delta g} + P_{nn}} \quad (23)$$

$$P_{ee} = P_{NN} - P_{N\Delta g}(P_{\Delta g\Delta g} + P_{nn})^{-1}P_{N\Delta g} \quad (24)$$

Now Eq. 19 can be evaluated in the frequency domain as follows:

$$F\{N\} = P_{N\Delta g}(P_{\Delta g\Delta g} + P_{nn})^{-1}F\{\Delta g\} \quad (25)$$

One can see immediately that Eqs. 24 and 25 are, formally, the frequency-domain equivalents of the LSC Eqs. 16 and 17. In fact, they can also be obtained starting from the general form of the equation for P_{ee} and estimating that $S = F\{s\}$ which makes P_{ee} minimum; such a derivation can be found in Sideris (1996). What makes them much more efficient, though, is that they require no matrix inversion as the -1 superscript in Eqs. 24 and 25 implies straightforward division at each frequency. Notice also that for noiseless data ($P_{nn} = 0$), Eq. 24 yields $P_{ee} = 0$, and Eq. 23 becomes $S = P_{N\Delta g}/P_{\Delta g\Delta g} = F\{N\}/F\{\Delta g\} = (2\pi\gamma q)^{-1}$. Note, however, that for the PSDs to be the Fourier transform of the covariance functions (CVs) used in collocation, these CVs have to be

stationary, which is not the case in practice with the noise CVs. Thus, the FFT method, although it is much more efficient than LSC, has to approximate nonstationary noise covariance functions (which are easily handled by LSC) by stationary ones; for details, see Sansò and Sideris (1997) and Kotsakis and Sideris (2001).

Computation of the Terrain Contributions

The terrain effect on Δg and the indirect effect on N are computed from approximations to Eqs. 32 and 33 in Sideris, ▶ “Geoid Determination, Theory and Principles”. Keeping only the terms for $r = 1$, these equations take the following form:

$$-\Delta g_{H_P} = c_P = \pi k \mathbf{L} [\rho (H - H_P)^2] \quad (26)$$

$$\delta N_{H_P} = -\frac{\pi k \rho}{\gamma} H_P^2 - \frac{\pi k}{3\gamma} \mathbf{L} [\rho (H^3 - H_P^3)] \quad (27)$$

With height data given in small area E around the computation point P , the planar approximation of the $\mathbf{L}$ operator can be used. In this case, the above equations become (Sideris 1990, 2016)

$$\begin{aligned} c_P &= \frac{1}{2} k \iint_E \rho \frac{(H - H_P)^2}{l^3} = \frac{1}{2} k \iint_E \frac{\rho H^2 - 2\rho H H_P + \rho H_P^2}{l^3} dx dy \\ &= \frac{1}{2} k [(\rho_P H_P^2) * l_P^{-3} - 2H_P [(\rho_P H_P) * l_P^{-3}] + H_P^2 (\rho_P * l_P^{-3})] \end{aligned} \quad (28)$$

$$\begin{aligned} \delta N_{H_P} &= -\frac{\pi k \rho}{\gamma} H_P^2 - \frac{k}{6\gamma} \iint_E \frac{\rho H^3 - \rho H_P^3}{l^3} dx dy \\ &= -\frac{\pi k \rho}{\gamma} H_P^2 - \frac{k}{6\gamma} [(\rho_P H_P^3) * l_P^{-3} - H_P^3 (\rho_P * l_P^{-3})] \end{aligned} \quad (29)$$

where $l_P^{-3} = (x_P^2 + y_P^2)^{-3/2}$. The above convolutions can be evaluated by FFT as follows:

$$\begin{aligned} c_P &= \frac{1}{2} k [F^{-1} \{F\{\rho_P H_P^2\} F\{l_P^{-3}\}\} + H_P^2 F^{-1} \{F\{\rho_P\} F\{l_P^{-3}\}\}] \\ &\quad - k H_P [F^{-1} \{F\{\rho_P H_P\} F\{l_P^{-3}\}\}] \end{aligned} \quad (30)$$

$$\begin{aligned} \delta N_{H_P} &= -\frac{\pi k \rho}{\gamma} H_P^2 - \frac{k}{6\gamma} [F^{-1} \{F\{\rho_P H_P^3\} F\{l_P^{-3}\}\} \\ &\quad - H_P^3 F^{-1} \{F\{\rho_P\} F\{l_P^{-3}\}\}] \end{aligned} \quad (31)$$

From the definition of the vertical derivative operator $\mathbf{L}$ in Eq. 21 in Sideris, ▶ “Geoid Determination, Theory and Principles” and the derivative property of the Fourier transform (Bracewell 2000; Sansò and Sideris 2013, Chapter 10, Appendix A), we can see that

$$F\{\mathbf{L}f\} = F\left\{\frac{\partial f}{\partial z}\right\} = 2\pi i w F\{f\} = -2\pi q F\{f\} \quad (32)$$

where i is the imaginary unit. We have also used the relationship $i w = -q$, which is a straightforward result of Laplace’s equation in the frequency domain:

$$F\{\nabla^2 f\} = [(i2\pi u)^2 + (i2\pi v)^2 + (i2\pi w)^2] F\{f\} = 0 \quad (33)$$

Now Eqs. 26 and 27 can also be evaluated by FFT using the analytical spectrum of the $\mathbf{L}$ operator as follows:

$$\begin{aligned} c_P &= k\pi [F^{-1} \{-2\pi q F\{\rho_P H_P^2\}\} - 2H_P F^{-1} \{-2\pi q F\{\rho_P H_P\}\} \\ &\quad + H_P^2 F^{-1} \{-2\pi q F\{\rho_P\}\}] \end{aligned} \quad (34)$$

$$\begin{aligned} \delta N_{H_P} &= -\frac{\pi k}{\gamma} \rho_P H_P^2 - \frac{\pi k}{3\gamma} [F^{-1} \{-2\pi q F\{\rho_P H_P^3\}\} \\ &\quad - H_P^3 F^{-1} \{-2\pi q F\{\rho_P\}\}] \end{aligned} \quad (35)$$

Such analytical representations of kernel functions, though not recommended for use in limited areas (Li and Sideris 1993), are often used in satellite altimetry applications, as discussed in the section that follows.

Evaluation of Satellite Altimetry Contributions

Like Stokes’s formula, the inverse Stokes, inverse Vening Meinesz, and deflection-geoid formulas employ kernels that are functions of the spherical distance ψ between the data and computation points; see Eq. 19 in Sideris, ▶ “Geoid Determination, Theory and Principles”. Therefore, when gridded data is available, they can be efficiently evaluated on the sphere by either the rigorous 1D FFT or the approximate 2D FFT formulas, completely analogous to Eqs. 4–9 used for Stokes’s integral. They will not be discussed further here, and the interested reader is referred to Hwang (1998) for detailed equations. Instead, we will concentrate here on the planar approximations with analytical kernel spectra.

On the plane, employing the same approximation for the sine and cosine of ψ as we did for Stokes’s formula, Eqs. 36–40 in Sideris, ▶ “Geoid Determination, Theory and Principles” simplify to

$$\Delta g_P = -\frac{\gamma}{2\pi} \iint_E \frac{N - N_P}{l^3} dx dy = -\gamma \mathbf{L}N = -\gamma \frac{\partial N}{\partial z} \quad (36)$$

$$\begin{aligned} \Delta g_P &= -\frac{\gamma}{2\pi} \iint_E \left(\xi \frac{y - y_P}{l^3} + \eta \frac{x - x_P}{l^3} \right) dx dy \\ &= -\frac{\gamma}{2\pi} (\xi_P * l_{\xi_P} + \eta_P * l_{\eta_P}) \end{aligned} \quad (37)$$

$$l_\xi = y/(x^2 + y^2)^{3/2} = -\partial l_N / \partial y, l_\eta = x/(x^2 + y^2)^{3/2} = -\partial l_N / \partial x \quad (38)$$

$$\begin{aligned} N_P &= -\frac{1}{2\pi} \iint_E \left(\xi \frac{y - y_P}{l^2} + \eta \frac{x - x_P}{l^2} \right) dx dy \\ &= -\frac{1}{2\pi} (\xi_P * l_{\xi_P} + \eta_P * l_{\eta_P}) \end{aligned} \quad (39)$$

$$l_y = y/(x^2 + y^2), l_x = x/(x^2 + y^2) \quad (40)$$

By making use of the derivative property of the Fourier transform, their evaluation by FFT is done as follows (Hwang 1998):

$$\Delta g_P = \gamma F^{-1} \{2\pi q F\{N_P\}\} \quad (41)$$

$$\Delta g_P = \gamma F^{-1} \left\{ \frac{i}{q} (vF\{\xi_P\} + uF\{\eta_P\}) \right\} \quad (42)$$

$$N_P = F^{-1} \left\{ \frac{i}{2\pi q^2} (vF\{\xi_P\} + uF\{\eta_P\}) \right\} \quad (43)$$

The planar form of Eq. 42 in Sideris, ► “Geoid Determination, Theory and Principles”, namely

$$\frac{\partial \Delta g}{\partial z} = -\gamma \left(\frac{\partial \xi}{\partial y} + \frac{\partial \eta}{\partial x} \right) \quad (44)$$

can also be evaluated by FFT from the expression

$$\left. \frac{\partial \Delta g}{\partial z} \right|_P = -2\pi \gamma F^{-1} \{ivF\{\xi_P\} + iuF\{\eta_P\}\} \quad (45)$$

Finally, Eq. 35 in Sideris, ► “Geoid Determination, Theory and Principles” that gives the deflections from altimetry-derived undulations is in planar approximation

$$\xi = -\frac{\partial N}{\partial y}, \eta = -\frac{\partial N}{\partial x} \quad (46)$$

and therefore its FFT-evaluation can be done via the expression

$$\xi_P = -2\pi F^{-1} \{ivF\{N_P\}\}, \eta_P = -2\pi F^{-1} \{iuF\{N_P\}\} \quad (47)$$

Summary

In this entry, we have outlined the steps in the remove-compute-restore technique that is employed in the numerical computations of geoid undulations. We have shown that most of the equations expressing the terrain and gravity effects on the geoid are convolution integrals, and we have described in detail how they can be efficiently evaluated by FFT given gridded data on the sphere or on the plane. In addition, computations by least-squares collocation have been outlined both in the space and in the frequency domain, in which the formula is equivalent to Wiener filtering and provides both noise filtering and accuracy estimates of the geoid through propagation of the data noise to the results. For a detailed treatment of FFT-based methods, the interested reader is referred to Chapter 10 in Sansò and Sideris (2013) and to Sideris (2016). The entry closes with the evaluation of various formulas used in gravity and geoid determination in the oceans using data from satellite altimetry.

Geoid Determination, Theory and Principles

Michael G. Sideris

Department of Geomatics Engineering, University of Calgary, Calgary, AB, Canada

Definition

The *geoid* is the equipotential surface of the Earth's gravity field, which best approximates the mean sea level at rest. Its determination requires (i) knowledge of the Earth's gravity potential and (ii) a way of geometrically representing the geoidal surface, which is done via its deviations – called geoid undulations N – from the surface of a known reference ellipsoid. The geometric representation is of particular importance given that the geoid is the reference surface, or datum, for the physically meaningful orthometric heights (see chapter ► “Height Systems, Vertical Datums and Their Unification”), often called heights above mean sea level.

Basic Principles: the Gravity, Normal, and Disturbing Potentials

The Earth's *gravity potential* W comprises the gravitational potential V and the centrifugal potential Φ :

$$W = V + \Phi = k \iiint_V \frac{\rho}{l} dv + \frac{1}{2} \omega^2 (x^2 + y^2) \quad (1)$$

V is a Newtonian potential due to the attraction of the masses, expressed as an integral of the mass density ρ over the volume v ; l is the Cartesian distance between the computation point and the mass element ρdv ; and k is Newton's gravitational constant. The centrifugal potential Φ is a function of the Earth's rotational velocity ω and the distance $p = (x^2 + y^2)^{1/2}$ from the rotation axis, namely, $\Phi = \omega^2 p^2/2$.

Due to our insufficient knowledge of the density distribution, Eq. 1 cannot be used directly to compute V and W . Nevertheless, a solution can be obtained by utilizing the fact that V is a harmonic function outside the masses, that is (a) it satisfies Laplace's equation

$$\nabla^2 V = \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0 \quad (2)$$

since the inverse distance in the integral of Eq. 1 clearly satisfies $\nabla^2 l^{-1} = 0$ and (b) it vanishes as $l \rightarrow \infty$. *Stokes's theorem* postulates that V can be determined everywhere in free space from its values on the boundary surface that encloses all masses and thus knowledge of the interior density distribution is not necessary.

The above problem formulation is called *Dirichlet's problem*, or first boundary value problem (BVP) of potential theory (Hofmann-Wellenhof and Moritz 2006). Its practical significance is rather limited since the potential is not a directly measurable quantity; it is important, however, for the expansion of V into a spherical harmonic series and for the relationship between V on the boundary surface and V in space (Poisson's integral). A more realistic BVP is *Neumann's problem*, or second BVP, in which the normal derivative $\partial V/\partial n$ is given on the boundary surface instead of V itself. This is because the first-order derivatives of W constitute the *gravity vector*

$$\mathbf{g} = \nabla W = \left(\frac{\partial W}{\partial x}, \frac{\partial W}{\partial y}, \frac{\partial W}{\partial z} \right)^T \quad (3)$$

which is observable. It is, however, the third BVP that is particularly important in practice; it uses observables on the boundary surface that are a linear combination of V and $\partial V/\partial n$. We will see in the following that the determination of geoid undulations from gravity anomalies – which are derived from the measurements taken with a gravimeter – is such a problem.

The determination of W is a nonlinear problem and is further complicated by the fact that W itself is not harmonic since $\nabla^2 W = \nabla^2 \Phi = 2\omega^2$. Both limitations can be overcome by linearization and approximating the shape, size, and gravity field of the Earth by an equipotential ellipsoid of revolution with the same mass M and same rotational velocity ω as the Earth. In this case, the gravitational potential of the reference ellipsoid V_e can be computed analytically, and its centrifugal potential Φ_e is the same as Φ . Its gravity potential, termed *normal potential* U , is

$$U = V_e + \Phi_e = V_e + \Phi \quad (4)$$

and its gradient is the *normal gravity vector*

$$\gamma = \nabla U = \left(\frac{\partial U}{\partial x}, \frac{\partial U}{\partial y}, \frac{\partial U}{\partial z} \right)^T \quad (5)$$

Both U and γ are analytical functions that can be computed from M , ω , and the semimajor and semiminor axes a , b of the reference ellipsoid; see Sansò and Sideris (2013), section 1.9. The difference between W and U at the same point is the *disturbing potential* T , which is obviously a harmonic function (since it is independent of the centrifugal potential, and since V_e , just like V , is harmonic being a function of the inverse distance):

$$T = W - U = V - V_e \quad (6)$$

$$\nabla^2 T = 0 \quad (7)$$

Now since U is known, the problem of determining W has been reduced to the problem of determining T , which is a third BVP provided that an appropriate observable would be available on the boundary surface. This is indeed the case, as it will be shown in the following.

The Stokes and Molodensky Geodetic BVPs

We select the geoidal surface Γ as the boundary surface that encloses all masses, we approximate Γ by the surface of the reference ellipsoid E , choose the normal potential U_o on E to be the same as the gravity potential W_o on the geoid, project a point P_o on the geoid on to a point Q_o on the ellipsoid along the ellipsoidal normal (see Fig. 1), and define the geoid undulation N as the distance $P_o Q_o$ and the *gravity anomaly* and *gravity disturbance* vectors as $\Delta \mathbf{g} = \mathbf{g}_{P_o} - \boldsymbol{\gamma}_{Q_o}$ and $\delta \mathbf{g} = \mathbf{g}_{P_o} - \boldsymbol{\gamma}_{P_o} = \nabla T$, respectively, with magnitudes

$$\Delta g = g_{P_o} - \gamma_{Q_o} \quad (8)$$

$$\delta g = g_{P_o} - \gamma_{P_o} \quad (9)$$

Geoid Determination, Theory and Principles, Fig. 1 Geometry of the Stokes BVP and the Molodensky BVP

We can now relate N to T , and Δg to T and its vertical derivative. Using Fig. 1, only first-order terms in Taylor expansions, and assuming – because the vertical deflection angle ε is very small – that the vertical derivatives along the ellipsoidal normal, normal plumb line, and actual plumb line are all the same, we can write

$$T_{P_o} = W_{P_o} - U_{P_o} = W_{P_o} - U_{Q_o} - \frac{\partial U}{\partial h} \Big|_{Q_o} \quad (10)$$

$$N = W_o - U_o + \gamma N = \gamma N$$

$$\delta g_{P_o} = -\frac{\partial T}{\partial h} \Big|_{P_o} = g_{P_o} - \gamma_{P_o} = g_{P_o} - \gamma_{Q_o} - \frac{\partial \gamma}{\partial h} \Big|_{Q_o} T \quad (11)$$

$$N = \Delta g - \frac{1}{\gamma} \frac{\partial \gamma}{\partial h} \Big|_{Q_o} T$$

Plumb lines are lines intersecting perpendicularly the surfaces of equal potential; that is, at every point, the gravity vector is tangent to the plumb line through that point.

The last two equations can now simply be written as

$$N = \frac{T}{\gamma} \quad (12)$$

$$\Delta g = \delta g + \frac{1}{\gamma} \frac{\partial \gamma}{\partial h} T = -\frac{\partial T}{\partial h} + \frac{1}{\gamma} \frac{\partial \gamma}{\partial h} T \quad (13)$$

Equation 12 is called *Bruns's equation* and provides N given T , while Eq. 13 holds only on Γ and it is called the *fundamental equation of physical geodesy*. The normal gravity on an ellipsoid with semi-axes a , b and normal gravity values at the equator and pole γ_a , γ_b , respectively, can be

computed from Somigliana's formula as a function of the point's latitude ϕ :

$$\gamma = \frac{a\gamma_a \cos^2 \phi + b\gamma_b \sin^2 \phi}{(a^2 \cos^2 \phi + b^2 \sin^2 \phi)^{1/2}} \quad (14)$$

Now *Stokes's BVP* can be defined as the problem of determining T , harmonic outside Γ , from measurements of Δg on the geoid that satisfy Eq. 13. This is a third BVP of potential theory, mathematically described by the partial differential equation of Eq. 7 with the boundary condition of Eq. 13, and it provides T on and outside Γ . Because of the assumption that the geoid encloses all masses, the influence of masses outside Γ must be computed and removed mathematically from the measurements via various types of terrain reductions. These require knowledge of the density distribution of the topographic masses and are described in this chapter in section ► [“TOPO-EUROPE: From the Deep Earth to the Surface of Continental Europe and Its Margins”](#).

Since all gravity measurements are taken on the surface of the Earth Σ , a more realistic way of defining the problem is to select Σ as the boundary surface rather than the geoid. This requires no terrain reductions but results in a mathematically more complicated BVP because Σ is not an equipotential surface and the gravity vector is not perpendicular to it. The determination of the Earth's surface from gravity anomalies on it is an oblique derivative problem called *Molodensky's problem* (Molodensky et al. 1962).

In *Molodensky's BVP*, the Earth's surface is approximated by a surface called the *telluroid* T , W on Σ is approximated by the normal potential U on T , and the gravity anomalies now are the difference between the gravity at the Earth's surface and the normal gravity at the telluroid, that is, $\Delta g = g_P - \gamma_Q$; see Fig. 1. The surface of T is defined as the set of points Q above the ellipsoid that correspond to points P on Σ having $U_Q = W_P$, $\phi_Q = \phi_P$, $\lambda_Q = \lambda_P$. This is called the *Marussi telluroid* and the ellipsoidal heights of its points are called *normal heights* H^* . The separation PQ between Σ and T is called *height anomaly* ζ . The height anomaly is the solution to the Molodensky BVP, as defined by Eqs. 7 and 13, where now the boundary condition holds on the telluroid rather than the geoid and Δg refers to the Earth's surface rather than the geoid.

Analytical Solutions to the Geodetic BVPs

Since $\nabla^2 T = 0$, T and therefore N can be expressed as a spherical harmonic series (see chapters ► [“Gravity, Global Models”](#) and ► [“Spherical Harmonic Analysis Applied to Potential Fields”](#))

$$N = \frac{kM}{\gamma r} \sum_{n=2}^{\infty} \left(\frac{a}{r}\right)^n \sum_{m=0}^n [C_{nm} \cos m\lambda + S_{nm} \sin m\lambda] P_{nm}(\sin \phi) \quad (15)$$

the coefficients of which, S_{nm} and C_{nm} , can be determined from, for example, gravity anomalies on the geoid using the orthogonality property of spherical harmonics. P_{nm} are Legendre functions and r , ϕ , λ are the coordinates of the computation point. Applying Eq. 15 to Eq. 13, the spherical harmonic series for Δg is

$$\Delta g = -\frac{kM}{r^2} \sum_{n=2}^{\infty} \left(\frac{a}{r}\right)^n (n-1) \sum_{m=0}^n [C_{nm} \cos m\lambda + S_{nm} \sin m\lambda] P_{nm}(\sin \phi) \quad (16)$$

Another analytical solution of this problem is given by *Stokes's integral* (see chapter ► [“Gravity Field of the Earth”](#)):

$$N = \frac{R}{4\pi\gamma} \iint_{\sigma} \Delta g S(\psi) d\sigma = \frac{1}{\gamma} \mathbf{S} \Delta g \quad (17)$$

where ψ is the spherical distance between data point and computation point, σ is the surface of a sphere of radius R (approximating the ellipsoid), and $\mathbf{S}$ is the Stokes integral operator. $S(\psi)$ is *Stokes's kernel function*

$$S(\psi) = \frac{1}{\sin(\psi/2)} - 6 \sin \frac{\psi}{2} + 1 - 5 \cos \psi - 3 \cos \psi \ln \left(\sin \frac{\psi}{2} + \sin^2 \frac{\psi}{2} \right), \quad (18)$$

$$\sin^2 \frac{\psi}{2} = \sin^2 \frac{\phi_P - \phi}{2} + \sin^2 \frac{\lambda_P - \lambda}{2} \cos \phi_P \cos \phi \quad (19)$$

Molodensky's problem can be solved in various ways. We give here the final solution by the *method of analytical continuation to point level*; detailed derivations can be found in Moritz (1980). In this method, the gravity anomalies are reduced to the equipotential surface passing through the computation point P ; see Fig. 1. They are denoted by $\Delta g'$ and are obtained by the formula

$$\Delta g' = \sum_{n=0}^{\infty} g_n,$$

$$g_n = - \sum_{m=1}^n (h - h_P)^m \mathbf{L}_m g_{n-m}, \quad (20)$$

$$g_o = \Delta g$$

$\mathbf{L}$ is the *vertical derivative operator* expressed in terms of surface values as follows:

$$\mathbf{L}_m = \frac{1}{m!} \mathbf{L}^m = \frac{1}{m!} \frac{\partial^m}{\partial h^m}, \quad (21)$$

$$\mathbf{L}f = -\frac{f}{R} + \frac{R^2}{2\pi} \iint_{\sigma} \frac{f - f_P}{l^3} d\sigma$$

where l is now the straight distance between the running point and the computational point P. Now, ζ at point P can be obtained by applying Stokes's integral operator $\mathbf{S}$ to $\Delta g'$:

$$\zeta = \frac{1}{\gamma} \mathbf{S} \Delta g' = \frac{1}{\gamma} \mathbf{S} \Delta g + \frac{1}{\gamma} \sum_{n=1}^{\infty} \mathbf{S} g_n = \sum_{n=0}^{\infty} \zeta_n \quad (22)$$

When the height anomaly is plotted above the ellipsoid, the resulting surface is called the *quasi-geoid*; see Fig. 1. Since $h = H^* + \zeta \approx H + N$, the geoid undulation can be estimated from the height anomaly by the following expression (Sansò and Sideris 2017):

$$N = \zeta + \delta\zeta, \quad (23)$$

$$\delta\zeta = H^* - H = \frac{\bar{g} - \bar{\gamma}}{\bar{\gamma}} H \approx \frac{\Delta g_B}{\gamma} H$$

where $\bar{g}$ and $\bar{\gamma}$ are the mean values of gravity and normal gravity along the plumb line between the geoid and Earth surface and the normal plumb line between the ellipsoid and the telluroid, respectively, and $\Delta g_B = \Delta g - A_B + F$ is the Bouguer gravity anomaly at the computation point; the definitions of A_B and F are given after Eq. 28. $H = \text{PP}_o''$ and $H^* = \text{QQ}_o$ are the *orthometric height* and *normal height*, respectively, of point P.

The Operational Solution to the Geodetic BVPs

In contrast to the analytical solution which is model-driven, the operational solution is data-driven. It starts from the data and information about their noise and the first and second moments (covariance functions) and estimates T as the “best” unbiased linear combination of the measurements. Besides being able to propagate the data noise into the results, it is also able to utilize as input, as well as predict, any functional of T . The harmonicity of T and the analytical relations between T and its functionals $f(T)$ are only used to derive the required covariance functions.

Mathematically, we want to estimate T , or more generally a signal vector $\mathbf{s}$ of functionals of T , from a vector of measurements

$\mathbf{l}$, which can contain Δg or any other $f(T)$, such as deflections of the vertical, second-order gradients, geoid undulations, etc.

$$\hat{\mathbf{s}} = \mathbf{H} \mathbf{l} \quad (24)$$

In order to estimate the matrix $\mathbf{H}$, we require that the variances of the estimation errors $\mathbf{e} = \hat{\mathbf{s}} - \mathbf{s}$ be minimum or that the error covariance matrix $\mathbf{C}_{ee} = E\{\mathbf{e}\mathbf{e}^T\}$ be minimum. By definition,

$$\begin{aligned} \mathbf{C}_{ee} &= E\{\mathbf{e}\mathbf{e}^T\} = E\{(\mathbf{H}\mathbf{l} - \mathbf{s})(\mathbf{H}\mathbf{l} - \mathbf{s})^T\} \\ &= \mathbf{H}E\{\mathbf{l}\mathbf{l}^T\}\mathbf{H}^T - E\{\mathbf{s}\mathbf{l}^T\}\mathbf{H}^T - \mathbf{H}E\{\mathbf{l}\mathbf{s}^T\} + E\{\mathbf{s}\mathbf{s}^T\} \\ &= \mathbf{H}\mathbf{C}_{ll}\mathbf{H}^T - \mathbf{C}_{sl}\mathbf{H}^T - \mathbf{H}\mathbf{C}_{ls} + \mathbf{C}_{ss} \\ &= \mathbf{C}_{ss} - \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1}\mathbf{C}_{ls} + (\mathbf{H} - \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1})\mathbf{C}_{ll}(\mathbf{H} - \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1})^T \end{aligned} \quad (25)$$

The last term in the right-hand side of the above equation is a nonnegative quadratic term, and therefore $\mathbf{C}_{ee}$ can only be minimum when that term is zero, that is, when $\mathbf{H} = \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1}$. Therefore,

$$\hat{\mathbf{s}} = \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1}\mathbf{l} \quad (26)$$

$$\mathbf{C}_{ee} = \mathbf{C}_{ss} - \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1}\mathbf{C}_{ls} \quad (27)$$

When the observations $\mathbf{l}$ contain noise $\mathbf{n}$, that is, consist of a signal component $\mathbf{t}$ and a noise component $\mathbf{n}$, then assuming that signal and noise are uncorrelated, the covariance matrices in the above equations become $\mathbf{C}_{ll} = \mathbf{C}_{tt} + \mathbf{C}_{nn}$, $\mathbf{C}_{ls} = \mathbf{C}_{ts}$, and $\mathbf{C}_{sl} = \mathbf{C}_{st} = \mathbf{C}_{ls}^T$. This method is generally known by the name of *least-squares collocation* (LSC). Knowledge of the covariance matrix of only one gravity field quantity is sufficient. From this, all other covariance matrices can be derived by covariance propagation. A complete discussion of LSC can be found in Moritz (1980) and in Chapter 5 in Sansò and Sideris (2013).

The Treatment of the Topography

The undulation of the geoid N can be obtained from the solution of Stokes's BVP provided that there are no masses outside the geoidal surface. There are many ways to mathematically account for the topographic masses, called *terrain reductions*, which preserve the total mass of the Earth but shift the masses above the geoid below it. *Helmert's second condensation reduction* will be briefly presented here as a representative from a number of possible terrain reductions. The masses above the geoid are basically condensed onto a layer on the geoid by (1) computing at point P and removing the attraction A_P of all masses above the geoid; (2) restoring at

P the attraction A_P^c of the masses condensed on a layer on the geoid with density $\sigma = \rho H$; and (3) downward-continuing the resulting gravity anomalies from P to P_o (see Fig. 2). This procedure gives Δg on the geoid computed from the approximate expression

$$\Delta g \approx \Delta g_P - A_P + A_P^c - \frac{\partial \gamma}{\partial h} H_P = \Delta g_P + \delta A + F \quad (28)$$

where the free-air gravity gradient $-\partial \gamma / \partial h$ is often used to approximate the gradient of the Helmert gravity anomalies, $(\Delta g_P + F)$ is the free-air gravity anomaly at P, and δA is the resulting attraction change. For a completely rigorous treatment of Helmert's second condensation reduction, Chapter 4 in Sansò and Sideris (2017) should be consulted.

The A and A^c terms in Eq. 28 are obtained by applying Newton's integral in Eq. 1 over the volume v of the relevant masses. For example, when the attraction A of all topographic masses above the geoid is computed, v is the volume of the masses between the geoidal surface and the surface of the topography. From Fig. 2, it can be seen that $A = A_B - c$, where $A_B = 2\pi k \rho H$ (for $\rho = \text{const}$) is the attraction of the infinite Bouguer plate through P called *Bouguer correction*, and c is the attraction of the residual topographic masses above and below the Bouguer plate, called the classical *terrain correction*. A complete set of formulas for the attractions, as well as the potentials, of the topography and the condensed topography can be found in Heck (2003).

δA is not the only change associated with this reduction. Due to the shifting of masses, the potential changes as well by an amount δT called the *indirect effect on the potential*:

$$\delta T = T_{P_o} - T_{P_o}^c \quad (29)$$

where T_{P_o} is the potential of the topographic masses at P_o and $T_{P_o}^c$ is the potential of the condensed masses at P_o . The corresponding *indirect effect on the geoid* is $\delta N = \delta T / \gamma$. Due to this potential change, the use of Δg from Eq. 28 into Eq. 17 produces not the geoid but a surface called the *co-geoid*, depicted by the *co-geoidal height* N^c above the reference ellipsoid. Thus, before applying Stokes's equation, the gravity anomalies must be transformed from the geoid to the co-geoid by applying a small correction $\delta \Delta g$ called the *indirect effect on gravity*

$$\delta \Delta g = -\frac{1}{\gamma} \frac{\partial \gamma}{\partial h} \delta T = -\frac{\partial \gamma}{\partial h} \delta N \quad (30)$$

The final expression giving N can now be written as

$$N = \frac{1}{\gamma} \mathbf{S}(\Delta g + \delta \Delta g) + \frac{1}{\gamma} \delta T = N^c + \delta N \quad (31)$$

where N^c is the co-geoidal height and δN is the indirect effect on the geoid; see Fig. 2.

Following Sideris (1990), δT and δA can formally be expressed using the planar approximation of the vertical derivative operator $\mathbf{L}$ of Eq. 21, that is, without the term $-f/R$, which then becomes zero since $R \rightarrow \infty$ when the spherical surface is approximated by the tangent plane. The potential change, for non-constant density ρ , is

$$\delta T = -\pi k \rho H_P^2 - 2\pi k \sum_{r=1}^{\infty} \frac{1}{(2r+1)!} \mathbf{L}^{2r-1} [\rho (H^{2r+1} - H_P^{2r+1})] \quad (32)$$

Geoid Determination, Theory and Principles, Fig. 2 Actual and condensed topography

and the attraction change is, to very good approximation (Martinec et al. 1993; Heck 2003), equal to the classical terrain correction c :

$$\delta A \approx c = 2\pi k \sum_{r=1}^{\infty} \frac{1}{(2r)!} \mathbf{L}^{2r-1} [\rho(H - H_P)^{2r}] \quad (33)$$

These series expansions are valid for low slopes of the terrain, namely, for $(H - H_P)/l_o \leq 1$, where l_o denotes the planar distance between running and computation point.

Sansò and Sideris (2017) have shown the equivalence between the solutions to the Molodensky BVP and the Stokes BVP with Helmert's second condensation reduction.

Another commonly used terrain reduction is the *residual terrain model* (RTM) reduction (Forsberg and Tscherning 1981; Sansò and Sideris 2013, Chapter 8). It computes at point P and removes only the high-frequency contributions of the topographic masses to gravity by, for example, computing the attraction of the masses between the actual topography and a very smooth “average topography” surface. The residual “geoid” produced by such reduced gravity anomalies is finally corrected by restoring the effect of the topographic masses that were removed. The RTM reduction yields a quasi-geoid rather than the geoid and, therefore, a final correction like the one in Eq. 23 must be applied in the end in order to recover the actual geoid undulation.

The Oceanic Geoid and Gravity from Satellite Altimetry

The only areas on Earth where, by definition, the geoid is almost directly observable are the oceans. From the difference between the ellipsoidal heights of altimetry satellites and the radar measurements to the surface of the sea, the ellipsoidal height h_s of the sea surface can be derived. h_s consists of the geoid undulation N and the sea surface topography (SST) H_s above the geoid. Thus, in principle, the geoid in the oceans can be derived from the expression

$$N = h_s - H_s \quad (34)$$

provided that a good model for the SST is available from oceanographic information. In addition, to minimize possible long-wavelength data biases, the *deflections of the vertical* are often derived numerically over the oceans as the slopes of the altimetry-derived geoid:

$$\xi = -\frac{\partial N}{r \partial \phi}, \quad \eta = -\frac{\partial N}{r \cos \phi \partial \lambda} \quad (35)$$

Although theory exists for the solution of overdetermined and altimetry-gravimetry BVPs, where given are gravity anomalies on the continents and geoid from altimetry and/or

gravity anomalies in the oceans, often in practice the oceanic geoid is also computed simply from Stokes's formula or from LSC using gravity data. Therefore, there is a need to obtain gravity anomalies in the oceans using as data altimetry-derived N and/or ξ, η .

Naturally, knowing N , one can use the following *inverse Stokes formula* to derive gravity anomalies in the oceans:

$$\Delta g_P = \frac{\gamma N_P}{R} - \frac{\gamma}{16\pi R} \iint_{\sigma} \frac{N - N_P}{\sin^3(\psi/2)} d\sigma \quad (36)$$

and then combine these gravity anomalies with the ones over land to produce a global set of gravity anomaly data which could be used in Stokes or LSC formulas to compute the global geoid. Note that the above equation has basically the form of the $\mathbf{L}$ operator acting on N , which, as expected, indicates that $\mathbf{L}$ and $\mathbf{S}$ are inverse operators. This can be proven easily, though rigorously, in planar approximation in the frequency domain; see details in chapter ► “Geoid Determination, Computational Methods”.

Gravity anomalies in the oceans can also be computed from the deflections of the vertical, using the *inverse Vening Meinesz formula*

$$\Delta g_P = \frac{\gamma}{4\pi} \iint_{\sigma} (\xi \cos \alpha + \eta \sin \alpha) H(\psi) d\sigma, \quad (37)$$

$$H(\psi) = \frac{\cos(\psi/2)}{2 \sin(\psi/2)} \left(-\frac{1}{\sin(\psi/2)} + \frac{3 + 2 \sin(\psi/2)}{1 + \sin(\psi/2)} \right) \quad (38)$$

where α is the azimuth of the line between the computation and the data point. A similar formula, termed the *deflection-geoid formula* (Hwang 1998), also exists that gives N from ξ, η :

$$N_P = \frac{R}{4\pi} \iint_{\sigma} (\xi \cos \alpha + \eta \sin \alpha) C'(\psi) d\sigma, \quad (39)$$

$$C'(\psi) = -\cot(\psi/2) + \frac{3}{2} \sin \psi \quad (40)$$

Another often used formula is the one that relates the vertical derivative of Δg to the horizontal derivatives of ξ and η . Starting from the spherical form of Laplace's equation

$$\begin{aligned} \nabla^2 T &= \frac{\partial^2 T}{\partial r^2} + \frac{2}{r} \frac{\partial T}{\partial r} + \frac{1}{r^2} \frac{\partial^2 T}{\partial \phi^2} - \frac{\tan \phi}{r^2} \frac{\partial T}{\partial \phi} + \frac{1}{r^2 \cos^2 \phi} \frac{\partial^2 T}{\partial \lambda^2} \\ &= \frac{\partial \Delta g}{\partial r} + \gamma \frac{\partial \xi}{r \partial \phi} - \frac{\tan \phi}{r} \gamma \xi + \gamma \frac{1}{r \cos \phi} \frac{\partial \eta}{\partial \lambda} = 0 \end{aligned} \quad (41)$$

and neglecting the small third term on the right-hand side, we obtain

$$\frac{\partial \Delta g}{\partial r} = -\gamma \left(\frac{\partial \xi}{r \partial \phi} + \frac{1}{r \cos \phi} \frac{\partial \eta}{\partial \lambda} \right) \quad (42)$$

It is clear that since Δg , ξ , η , N , and their various derivatives are all functionals of T , they could all be used as input in LSC to predict both Δg and N in the oceans. Therefore, collocation could be used either to predict directly undulations and anomalies in the oceans from any gravity field quantity, or to densify or interpolate data necessary for the efficient evaluation of integrals like inverse Stokes or inverse Vening Meinesz. Details can be found in chapter ► [“Geoid Determination, Computational Methods”](#).

Summary

We have discussed briefly how the geoid is defined and how it can be estimated either analytically as the solution of the third BVP (or Molodensky’s BVP) from gravity anomalies all over the Earth or as a “best” unbiased linear combination of all available gravimetric data using least-squares collocation. In either case, data have to be reduced to the geoid via an appropriate terrain reduction. The methodology used in the numerical determination of geoid undulations is described in chapter ► [“Geoid Determination, Computational Methods”](#). Readers interested in obtaining a more comprehensive view of gravity field approximation and geoid determination are referred to Sansò and Sideris (2013, 2017) and are encouraged to also read the other chapters on geoid and gravity included in this volume. Finally, with dedicated gravity satellites like GRACE and its follow-on mission GRACE-FO, the computation of temporal variations of the geoid and its application to other geosciences is now possible; see chapter ► [“Gravity Field, Temporal Variations from Space Techniques”](#). This, however, is beyond the scope of this short entry and will not be discussed here.

Synonyms

Depth of Moho surface is the same as the thickness of the lithosphere; Direct gravimetric problem, aka forward modeling; Geoidal height, aka geoid undulation; Moho surface, aka compensation level for the Airy-Heiskanen isostatic hypothesis; Ocean bottom depth, aka bathymetry; Schiaparelli’s body, aka body of nil external potential; Sea surface topography (SST), aka dynamic topography; Spectral transfer function, aka admittance; Stokes’s integral truncated to the spherical distance of ψ_0 , aka inner zone contribution to Stokes’s integral

Definition

Direct gravimetric problem is defined as follows: “Given the distribution of density within the Earth, derive the (external) gravity field the density generates.”

The *inverse gravimetric problem* (GIP) reads: “Given the external gravity field of the Earth, derive the distribution of density implied by the field.”

Introduction

The main goal of geophysics is to learn about the physical processes as well as properties of the material within the Earth. These are studied by means of measurements (data) collected on the surface of the Earth and above it and, to a very limited degree, also in very shallow probes inside the Earth. The discussion of the data to be collected and the techniques to be used to study the physical processes and material properties within the earth are what this book is all about.

The focus of this section is on gravity field, the geoid in particular, to the exclusion of all other, such as seismological, magnetic, electrical, heat flow data. The only attribute of the Earth that can be studied by means of gravity is the mass density variations as gravity is the acceleration caused by mass attraction. Three aspects of gravity field can be used for these studies: gravity acceleration, the deflection of the vertical, and gravity potential. Gravity acceleration, in the guise of gravity anomalies, are discussed in *Gravity Anomalies, Interpretation*, the deflections of the vertical are introduced in *Geodesy, Physical* and for an in-depth view of the definition of geoid the reader is advised to consult *Geoid*.

One of the general properties of the gravity field is that deep-seeded density anomalies have long wavelength signature in the gravity field while shallow density anomalies have short wavelength signature. Consequently, if one wishes to study shallow density features, one looks at the short wavelength part of gravity field and if one wishes to study deep-seeded features, one looks at the long wavelength part. This is, of course, true only as a general principle as there exist also shallow features of large lateral extent that have long wavelength signatures.

When it comes to the interpretation of gravity field, the data of choice by exploration geophysicists, that is, people looking for ore, hydrocarbon, and other deposits, are gravity anomalies. The reason for this is that these data are bountiful on land, relatively cheap, and they contain all the short wavelength information. Observed deflections of the vertical as supplied by national geodetic offices are less popular as a source of information as they are not very accurate, and they are few and far apart. But we may live to see this situation change with the advent of Digital Zenith Cameras (Hirt et al. 2010).

Gravity potential data, such as the values of disturbing potential – divided by the value of gravity to convert them to the geoid – are much smoother than the first two kinds. This means that the short wavelength content is missing. We know that all three descriptors of gravity field we discuss here are functionally related: gravity acceleration at a point is a total gradient of the potential at that point, the deflection of the vertical at a point is a horizontal gradient of the equipotential surface passing through that point. Thus, there is nothing to stop us from using the potential data, the geoid, in such a way as to evaluate either the gravity anomalies or the deflections of the vertical and use these for the interpretation, is there?

That can be done of course, but this procedure cannot reconstitute the high frequency content as it has not been there to begin with. Thus, the conversion would not help and it is better to use the geoid as is; this is the thesis of the book (Vaníček and Christou 1993). The direct use of the geoid has caught an interest of interpreters as the marine geoid data from satellite altimetry became quite reliable and freely available in the past 25 years.

Direct Problem

Suppose we know the density distribution $\rho(\mathbf{r})$ within the Earth. Then we can determine the potential $V(\mathbf{r})$ outside the earth in two different ways. We can use the well-known Newton's integral to get the gravitational potential in a spatial form at any point external to the Earth as (Vaníček and Krakiwsky 1986, Equation 20.48)

$$V(r, \Omega) = G \int_{\Omega_0}^{r_t(\Omega)} \frac{\rho(r', \Omega')}{|\mathbf{r} - \mathbf{r}'|} (r')^2 dr' d\Omega', \quad (1)$$

where G is Newton's gravitational constant, r is the radial distance from the center of the Earth, Ω is the geocentric direction composed of colatitude θ and longitude λ , Ω_0 is the full geocentric solid angle, r_t is the distance from the center of the Earth to the topographical surface of the Earth.

Alternatively, the reciprocal distance $\frac{1}{|\mathbf{r} - \mathbf{r}'|}$ can be developed into a series of fully normalized spherical harmonic complex functions Y_{jm} to yield

$$V(r, \Omega) = \frac{GM}{a} \sum_{j=0}^{\infty} \left(\frac{a}{r}\right)^{j+1} \sum_{m=-j}^j A_{jm} Y_{jm}(\Omega), \quad (2)$$

where M is the mass of the Earth, a is the major semiaxis of the best fitting Earth ellipsoid, and A_{jm} are the gravity potential coefficients. The potential coefficients can be evaluated from the known density $\rho(\mathbf{r}) = \rho(r, \Omega) = \rho(r, \theta, \lambda)$ within the Earth as

$$A_{jm} = \int_{\Omega_0} \int_{r=0}^{r_i(\Omega)} \rho(r, \Omega) G_{jm}(r, \Omega) dr d\Omega, \quad (3) \quad \text{where}$$

where the integration kernel G_{jm} is given by Martinec in Vaníček and Christou (1993, Chap. 7, Equations 13 and 14)

$$G_{jm}(r, \Omega) = \frac{4\pi}{Ma^j(2j+1)} r^{j+2} Y_{jm}^*(\Omega). \quad (4)$$

Here $*$ denotes a complex conjugate. This is the spherical harmonic form of potential V , a dual form to the spatial form (Eq. 1 above) – these two forms can be transformed into each other, back and forth any time. The relation between potential V and the geoid undulation N is explained in *Geodesy, Physical*.

The direct approach, also known as forward modeling, can be used for solving some geophysical problems. Notably, it can be used to determine the depth of Mohorovicic's surface, the surface that divides the asthenosphere (density about 3.2 g cm^{-3}) from the lithosphere (density about 2.67 g cm^{-3}). The Moho surface is also the compensation level for the Airy-Heiskanen isostatic hypothesis. The depth of the Moho surface, or the lithospheric (crustal) thickness derived this way, assuming the most realistic asthenospheric density and described by a spherical harmonic series of a limited degree and order is shown on a web page <http://geology.com/articles/mohorovicic-dis-continuity.shtml>. The displayed map was compiled by US Geological Survey in 1999.

Inverse Problem

The determination of density $\rho(\mathbf{r})$ as a function of position $\mathbf{r}$ from any of the gravity field attributes, that is, gravity anomaly $\Delta g(\mathbf{r})$, the components of the deflection of the vertical ($\xi(\mathbf{r}), \eta(\mathbf{r})$), or the geoidal height $N(\mathbf{r})$, is known as the inverse gravity problem (GIP). The non-uniqueness of GIP was known already to Schiaparelli, who in 1875–1876 was speaking of “gravitationally transparent bodies,” specific distributions of density that do not generate any gravitational attraction outside the Earth. A complete mathematical description of a Schiaparelli's body was formulated by Vaníček and Kleusberg (1985) as follows: for arbitrary values of coefficients $c_{ljk}^{(i)}$ the following “body”:

$$\begin{aligned} \theta \in < -\frac{\pi}{2}, \frac{\pi}{2} >, \lambda \in < 0, 2\pi >, r \in < 0, 1 >: \\ \tilde{\rho}(\mathbf{r}) = \sum_{i=0}^{\infty} \sum_{l=0}^i \sum_{j=0}^{\infty} \sum_{k=0}^j c_{ljk}^{(i)} \phi_{ijk}(\mathbf{r}), \end{aligned} \quad (5)$$

$l \neq j$

$$\begin{aligned} \forall i, j = 0, 1, \dots, k \leq j : \phi_{ijk}(\mathbf{r}) \\ = J_i(3, 3, r) \left[Y_{jk}^c(\Omega), Y_{jk}^s(\Omega) \right], \end{aligned} \quad (6)$$

J_i are normalized Jacobi polynomials (Abramowitz and Stegun 1964) and Y_{jk}^c, Y_{jk}^s are the cosine and sine parts of spherical harmonic functions, has a nil external potential outside the ball of radius 1. The consequence of this behavior is that if one tries to interpret the external gravity potential in terms of internal density distribution, any distribution that conforms to Eq. 5 can be randomly and legitimately added to the solution.

If the GIP does not have a unique solution, does it make any sense to even think about using gravity in studying the density distribution? True, it is not possible to take the gravity field outside the Earth and invert it uniquely into the density distribution within the Earth. But the external gravity field, particularly the geoid in our context here, can be used together with other data to get useful information on density.

Truncated Geoid

There is a variety of techniques used in geophysical exploration to interpret gravity information obtained on the surface of the Earth in terms of anomalous density. One interesting approach uses the truncated geoid to determine the depth of a spherical, i.e., ball-like, density anomaly, where by “truncated geoid” we understand the following integral:

$$N^{\psi_0}(P) = \frac{R}{4\pi\gamma} \int_{C_{\psi_0}} \Delta g(Q) S(P, Q) d\sigma, \quad (7)$$

which represents the contribution of gravity to the geoid within the spherical cap C of a radius ψ_0 . It can be viewed as the Stokes integral over the whole Earth, truncated to the spherical distance ψ_0 , where P is the point of interest, Q is the dummy point in the integration, $S(P, Q) = S(\psi)$ is the Stokes spherical kernel and $d\sigma$ is the surface element of the integration sphere of radius R .

It is the change of the truncated geoid with respect to the truncation parameter ψ_0 ,

$$\frac{dN^{\psi_0}}{d\psi_0} = \lim_{\Delta\psi_0 \rightarrow 0} \frac{N^{\psi_0+\Delta\psi_0} - N^{\psi_0}}{\Delta\psi_0}, \quad (8)$$

that is of real interest. At the location of the density anomaly, the sequence of surfaces or profiles $\frac{dN^{\psi_0}}{d\psi_0}$ displays a dimple for a specific value of ψ_0 – see Fig. 1 (from Vajda and Vaníček

Geoid Undulation, Interpretation,

Fig. 1 Sequence of profiles of the change of the truncated geoid with respect to the truncation parameter ψ_0 that shows the onset of the dimple for a value of $\psi_0 = 2.5^\circ$

1999). This specific value of ψ_0 is almost linearly related to the depth of the anomaly.

In Fig. 2, geoid from an area in Southern Slovakia is shown. Just northeast of the geographical center of the area, there is a local geoid low, known as “Kolarovo anomaly,” that has been intriguing geophysicists for some time. It has been postulated by several authors that the center of mass of the density anomaly responsible for the shown pattern is about 9.5 km bellow the Earth surface. The application of the truncated geoid technique shows an estimate of 8.7 km (Vajda et al. 2002).

Some Other Applications

In addition to the above-discussed applications, geoid can be used in many other ways; one of those applications is studying tectonic forces. Interested reader may read about the involved concepts in *Gravity, Global Models*. Bowin, in his earlier studies (1991), postulated that the $4\text{--}10^\circ$ geoid undulations are consistent with the present zones of subducted tectonic slabs. His postulate has more recently been confirmed by Ricard et al. (2006). These authors also agree with Bowin’s speculation (1983) that only the deepest Earth’s mass anomalies cause geoid undulations of $2\text{--}10^\circ$.

Casenave in Vaniček and Christou (1993, Chap. 13) discusses the use of the geoid in studying different isostatic compensation models using the spectral transfer function, aka admittance in the “theory of systems” parlance. She studies the mechanical behavior of oceanic tectonic plates (flexure under seamount loading) and thermal evolution of oceanic lithosphere. Ricard et al. (2006) show that the elasticity of the lithosphere affects the geoid between 200° and 250° . Casenave also argues that the signatures of oceanic hot spots in the geoid are in the medium wavelength of $n \in (5, 20)$ and in 1–10 m in range.

Geoid Undulation, Interpretation, Fig. 2 Geoid in the area of “Kolarovo anomaly” in Southern Slovakia. (Courtesy of J. Janak, Slovak University of Technology)

It may be worth mentioning that meteorite craters are often clearly discernible in detailed geoid maps. The Manicouagan crater in Eastern Canada (location: $N 51^\circ 23'$ and $W 68^\circ 42'$) makes a very clear imprint on the geoidal map.

The last applications of the geoid we want to show here concern physical oceanography and the oceans in general. A very good overview of this topic by Nerem and Koblinsky is in Vaniček and Christou (1993, Chap. 16). Geoid, being an equipotential (level) surface, should be represented by the mean sea level if seawater were homogeneous, which, of course, it is not. As a result, the mean sea level is not in equilibrium and currents develop. Some time after the initiation of this motion, these currents reach a steady state, called geostrophic, and swirl around the globe in a perpetual motion attenuated only by friction.

The equation that describes the geostrophic motion is ascribed to Navier and Stokes, and it reads as follows:

$$\mathbf{V} + (\mathbf{V} \cdot \nabla)\mathbf{V} + 2\boldsymbol{\Omega} \times \mathbf{V} = \frac{-\nabla p}{\rho} + \mathbf{g} + \mathbf{F}, \quad (9)$$

where $\mathbf{V}$ is the flow velocity vector, $\boldsymbol{\Omega}$ is the rotation vector of the Earth, p is the hydrostatic pressure, ρ is the seawater density, $\mathbf{g}$ is the gravitation vector, and $\mathbf{F}$ is the vector representing frictional forces (ibid. Eq. 1). This equation, together with measurements taken at sea, is then used to derive the height of the sea surface above the geoid, which is called the “dynamic topography.”

As discussed above, the instantaneous sea surface has been monitored by a technique called satellite altimetry for years. This surface represents, of course, the sum of the geoidal height and the dynamic topography. Subtracting the geoid from the measured sea surface yields the dynamic topography that can be easily converted into information about currents. Conversely, subtracting the dynamic topography from the measured surface yields the geoid. Interested reader can refer to following URL <http://www.aviso.oceanobs.com/en/data/products/auxiliary-products/index.html> for more detailed information.

Last but not least, the geoid obtained from satellite altimetry can be used to calculate the ocean bottom depth, aka bathymetry (Sandwell et al. 2006). The principle used in these calculations is the same as the one used in the determination of the Moho surface. Acknowledging that the ocean bottom is a surface that divides the crust (of an average density of 2.67 g cm^{-3}) from the layer of water (of an average density of 1.03 g cm^{-3}), forward modeling it then used to yield the ocean bottom surface.

Summary

The geoidal height (geoid undulation) is a quantity that can be quite readily interpreted in terms of density distribution within the Earth. The main application is in studying the processes that take place deep within the Earth, but even shallower density anomalies have an impact on a geoid map. Nowadays, when sea surface height measured by satellite altimetry is freely available, marine geoid has become a particularly handy tool to use.

Geomagnetic Excursions

Martha Schwartz

Department of Earth Sciences, University of Southern California, Los Angeles, CA, USA

Synonyms

Excursions were initially observed as “tiny wiggles” in marine magnetic anomalies (LaBreque et al. 1977) and were termed “cryptochrons” by Cande and Kent (1992a, b).

Definition

Geomagnetic Excursions are periods of unusually high-amplitude secular variation (see ► [“Geomagnetic Field, Secular Variation”](#)). They are usually defined as short-term deviations of the Virtual Geomagnetic Dipole (VGP) more than $40\text{--}45^\circ$ from the geographic poles (see ► [“Geomagnetic Field, Global Pattern”](#)).

Geographical and Temporal Extent

Excursions last for up to a few thousand years during times of otherwise stable field polarity. The unusual directions, which sometimes represent regionally complete reversals (see ► “[Geomagnetic Field, Polarity Reversals](#)”), are always accompanied by globally correlative low levels of field intensity (see ► “[Paleomagnetic Field Intensity](#)”). Low intensity starts earlier than the anomalous directions and outlasts them. There is some emerging evidence that excursions are global in extent. However, uncertainties in age control limit the ability to establish synchronicity among directional records recovered from different regions. Inadequate paleomagnetic recording may also cause excursions to be missed at certain localities. Lava flows do not provide a continuous record of field behavior, and sediment records of short-term directional field behavior may be smeared due to low sedimentation rates (see ► “[Geomagnetic Field, Measurement Techniques](#)”).

The frequency and duration of geomagnetic excursions are also open issues. Answers depend on recovering further high-quality replicated records, as well as better understanding of their regional versus global extent. There is reproducible evidence for 17 time intervals within the Brunhes Chron with at least regionally verifiable magnetic field excursions (Lund et al. 2006). Two well-recorded examples of excursions are the Laschamp Excursion, first noted in French lavas (Bonhommet and Babkine 1967), which occurred about 40 ka, and the Blake Event (first observed by Smith and Foster 1969) from about 120 ka.

The Fig. 1, reproduced from Lund et al. (2005), is a high-resolution record of the Laschamp Excursion, as recovered from the Blake Outer Ridge in the North Atlantic Ocean.

Field Configuration During Excursions

Complete understanding of the mechanism causing excursions depends on improved mapping of the global field geometry during excursive intervals. Roberts (2008) summarized three suggested excursionary field configurations. (1) The field remains largely dipolar but wanders away from the rotational axis. In this case VGP's would be consistent regardless of sampling site. (2) The ratio of non-dipole and dipole field components becomes very high. In this case VGPs would depend strongly on the sampling site. (3) Relatively localized sources in the outer-core produce regional excursions (see ► “[Geomagnetic Field, Theory](#)”).

Several numerical dynamo models are able to simulate magnetic field excursions for certain choices of boundary conditions. But model numerical simulations are limited in spatial or temporal resolution due to presently limited computer technology (Glatzmaier 1999).

Geomagnetic Excursions, Fig. 1 Paleomagnetic secular variation and relative paleointensity (small dots are original data, large dots are 3-pt running average) records from Blake Outer Ridge core JPC14 for the time interval of the Laschamp Excursion. NRM after 20 mT demagnetization was used outside the excursion interval and NRM characteristic remanences were used in the excursion interval. These records show the same distinctive interval of low paleointensity seen in other cores (Figs. 2 and 3). But it contains a much more dramatic pattern of directional variability that we consider to be a more accurate and high-resolution record of the Laschamp Excursion as seen on the Blake Outer Ridge. The dashed lines indicate three time intervals where directions in this record are almost identical to the Laschamp Excursion directions seen in Europe (open diamonds). These three intervals also have similar paleointensity lows. Boxes at top indicate intervals of clockwise (C) or counterclockwise (CC) looping (circularity) in the directional data

Origin

The most widely accepted explanation for the origin of geomagnetic excursions comes from Gubbins (1999). According to this theory, the outer core reverses briefly but the solid inner core, which has a magnetic diffusion time on the order of 3000 years, does not reverse. In the case in which the inner core did have time to turn around, the event would be recorded as a full field reversal (see ► “[Geomagnetic Field, Polarity Reversals](#)”).

Summary

Geomagnetic excursions are brief periods of anomalous directions coupled with low field intensity. Their spatial

extent, duration, and causative mechanism are under study. A review paper by Laj and Channell (2007) provides an excellent summary of the research to date.

Geomagnetic Field, Global Pattern

Susan Macmillan
Geomagnetism Team, British Geological Survey,
Edinburgh, UK

Definition

The geomagnetic field is the Earth's magnetic field and in this chapter we describe how its pattern is mapped at the surface of the Earth through time.

Introduction

The geomagnetic field is generated in the fluid outer core region of the Earth by electrical currents flowing in the slowly moving molten iron. In addition to sources in the Earth's core, the geomagnetic field observable at the Earth's surface has sources in the crust and in the ionosphere and magnetosphere. The signal from the core dominates, accounting for over 95% of the field at the Earth's surface. The geomagnetic field varies on a range of scales, both temporal and spatial; the description of the variations made here concentrates on the recent spatial and temporal variations of the field with origins in the Earth's core that can be surmised from observations made over the last four centuries.

Observations

The geomagnetic field is a vector quantity, having magnitude as well as direction. The direction of the geomagnetic field has been directly observed and recorded for at least 400 years beginning with observations of the angle in the horizontal plane between true north and the magnetic field vector, known as declination or magnetic variation. In 1634 it was realized by Henry Gellibrand that declination in London was changing with time when he compared his observations with those made by Edmund Gunter 12 years earlier. Since then this important discovery of secular variation has ensured regular observations of the magnetic field through time. Measurements of declination were important for navigation across the oceans, and a source of early observations is ships' log-books (Jackson et al. 2000). Before long it was also realized that other elements of the geomagnetic field were of interest, in particular the angle of dip of the magnetic field vector from the horizontal known as inclination, and this was also measured. However, it was not till 1832 when Carl Friedrich Gauss established his technique for measuring absolute intensity did we have accurate measurements of the magnitude of the geomagnetic field.

As demands on accuracy and interest in the geomagnetic field increased, permanent observatories began to be established. Since the 1840s the number of observatories around the world has slowly increased to a peak of about 180 in the late 1980s and early 1990s but is about 160 in recent times. The advent of the proton precession magnetometer and the fluxgate magnetometer in the twentieth century considerably eased the automation of observatories during this time. However, regular manual absolute observations, nowadays of declination and inclination using a fluxgate theodolite, are necessary to maintain accurate baseline control over long periods of time. There are also networks of repeat stations providing data over extensive areas from which country-wide magnetic charts could be derived. More recently, magnetic measurements made by satellites have

become important in determining the pattern of the geomagnetic field. In particular, vector data from Magsat (1979–1980), Ørsted (1999–2013), CHAMP (2000–2010), and Swarm (2013–) have all been utilized in the production of recent spherical harmonic models of the geomagnetic field.

Spherical Harmonic Analysis

Till the 1950s magnetic charts at a given epoch for use in navigation depended on manually drawing contours through the observations (Malin 1971). Although spherical harmonic analysis had been developed in 1839 by Carl Freidrich Gauss, it was not routinely used to fit mathematical models to the observations till the advent of computers. Before computers spherical harmonic analysis required that the data be in the form of values of one or more of the orthogonal components X , Y , and Z of the geomagnetic field (magnetic intensities in the northerly, easterly, and vertically down directions) at points regularly spaced in latitude and longitude (Barraclough 1978). This involved the intermediate stage of interpolating values from manually drawn contour charts.

The mathematical and physical basis for spherical harmonic analysis is now given. In a source-free region, the Earth's magnetic field $\mathbf{B}$ is the negative gradient of a magnetic potential V that satisfies Laplace's equation:

$$\mathbf{B} = -\nabla V \quad \text{where} \quad \nabla^2 V = 0$$

A solution to Laplace's equation for the magnetic potential arising from sources inside the Earth at a given epoch is given by:

$$V(r, \theta, \lambda) = a \sum_{n=1}^{n_{\max}} \left(\frac{a}{r}\right)^{n+1} \sum_{m=0}^n \times (g_n^m \cos m\lambda + h_n^m \sin m\lambda) P_n^m(\theta)$$

In this equation r , θ , λ are geocentric coordinates (r is the distance from the center of the Earth, θ is the colatitude, i.e., $90^\circ - \text{latitude}$, and λ is the longitude), a is a reference radius for the Earth (6371.2 km), g_n^m and h_n^m are the spherical harmonic Gauss coefficients of degree n and order m , $P_n^m(\theta)$ are the Schmidt semi-normalized Legendre functions, and $n_{\max}$ is the maximum degree of the spherical harmonic expansion. If the observations of the magnetic field are spread over time, the magnetic potential and corresponding Gauss coefficients are also dependent on time with splines being commonly used.

Maps of the Geomagnetic Field

It is worth noting here that the first published map of the geomagnetic field is that of declination made in 1701 by

Edmond Halley. It was based on declination observations made during a magnetic survey expedition under naval command and covered the Atlantic Ocean (Clark and Barraclough 2001).

The maps that we show here are based on spherical harmonic models. Nowadays there are many such models of the geomagnetic field and here we look at two examples. One is the *gufm1* model which is derived from four centuries of magnetic field observations (Jackson et al. 2000) and extends to spherical harmonic degree 14 with B-splines being used to fit the variations in time from 1590 to 1990. It has smoothness imposed in both the spatial and temporal domains. The other model is the International Geomagnetic Reference Field (Thébault et al. 2015) produced under the auspices of the International Association of Geomagnetism and Aeronomy (IAGA). It extends to spherical harmonic degree 10 till 1995 and thereafter extends to degree 13. The variations in time from 1900 to 2020 in the IGRF are assumed to be piecewise linear and there is effectively no smoothness imposed in either the spatial or temporal domains. The final IGRF coefficients are made up of weighted averages of candidate sets of coefficients from (mostly) unregularized models.

Using the *gufm1* model, plots of declination and inclination at 1600, declination, inclination, and total intensity at 1950 are shown in Figs. 1 and 2. Using the 12th generation IGRF, plots of the magnetic elements at 2015 and their rates of change are shown in Figs. 3, 4, 5, 6, 7, 8, and 9. The rates of change plots are derived from a predictive secular variation model which extends to spherical harmonic degree 8. Up-to-date maps, and on-line calculators are available from a number of websites, for example, <https://geomag.bgs.ac.uk/navigation.html> and <https://ngdc.noaa.gov/geomag/WMM/DoDWMM.shtml>.

Features of note on these maps are the dip equator and dip poles in the maps of inclination (Figs. 1, 2, and 8) and the area of weak magnetic field in the South Atlantic, and strong magnetic field near the poles in Figs. 2 and 9. The dip equator is where the magnetic field is horizontal (inclination = 0°) and a current system is set up in the upper atmosphere called the equatorial electrojet. The dip poles (also called magnetic poles) are locations where the magnetic field is, on average, vertical. Another set of poles is the dipole poles or geomagnetic poles. Their positions can be derived from the degree 1 spherical harmonic coefficients (g_1^0 , g_1^1 , and h_1^1). Associated with the geomagnetic poles, in approximately oval shaped loci, are the auroral electrojets in the upper atmosphere. The electrojets, particularly the auroral electrojets, generate rapid time-varying magnetic fields of significant amplitude.

Recent Changes in the Geomagnetic Field

From a comparison of the declination maps in Figs. 2 and 7, it can be seen that the zero contour (the agonic line) is

Geomagnetic Field, Global Pattern, Fig. 1 Declination and inclination at 1600.0 (degrees) computed from the *gufm1* model

Geomagnetic Field, Global Pattern, Fig. 2 Declination, inclination (degrees), and total intensity (nT) at 1950.0 computed from the *gufm1* model

moving slowly westwards with time. This westwards movement of the magnetic field pattern at the Earth's surface, particularly prevalent in the Atlantic hemisphere, is related to the motion of fluid at the core surface

slowly westwards, dragging with it the magnetic field lines.

At high northern latitudes from 2000 to 2020, the motion of the north dip pole has been more than 50 km per year and

Geomagnetic Field, Global Pattern, Fig. 9 Total intensity (nT) at 2015.0 and its rate of change (nT/year) for 2015.0–2020.0 computed from IGRF 12

Geomagnetic Field, Global Pattern, Fig. 10 Decline of the whole, and dipolar part of the geomagnetic field at the Earth's surface and the growth of the nondipolar part since 1900, computed from IGRF-12

sometime during 2017/2018 it reached its highest latitude (86.6°N). According to the latest IGRF, we are now seeing a deceleration of this motion, but the pole is still moving at roughly 40 km per year, and heading southwards. In contrast, the southern dip pole, near Antarctica, has moved relatively little in the past few hundred years.

Using IGRF-12 to compute the root mean square magnetic field vector at the Earth's surface arising from all spherical harmonic terms ($n \leq 10$), the centered dipole terms ($n = 1$), and the nondipole terms ($1 < n \leq 10$), it can be seen in Fig. 10 that since 1900 the geomagnetic field is weakening overall by becoming less dipolar. However, the nondipolar part is strengthening. This may have consequences for the trajectories of energetic charged particles that enter the Earth's magnetosphere. One manifestation of this is the deepening, and westwards movement, of the South Atlantic Anomaly, the region where the geomagnetic field is weaker than elsewhere (see Figs. 2 and 9). Energetic charged particles are able to penetrate closer to the Earth and cause a radiation hazard for satellites passing through this region.

Superimposed on these gradual changes of the magnetic field are the so-called geomagnetic jerks. They are relatively abrupt (duration of months) changes in the second time derivative, or secular acceleration, of the magnetic field. The first observed geomagnetic jerk was that around 1969, and since the late nineteenth century when direct and continuous measurements of the Earth's magnetic field have been available, geomagnetic

jerks have also been widely accepted to have occurred around 1925, 1978, and 1991. These jerks are most readily observed in the first time derivative of the easterly intensity at European observatories (Fig. 11). More recent jerks are also being detected, sometimes with help of data from satellites.

Various analysis techniques have been applied to jerks to investigate specific aspects of their temporal and spatial characteristics. For example, Brown et al. (2013) used minimal a priori information to accurately time the occurrence of jerks around the world and establish their amplitudes using observatory data. The variable timing is particularly interesting for studies of the geodynamo though the effects of varying conductivity in the deep mantle on the arrival time of the jerk signals at the Earth's surface cannot be discounted (Pinheiro et al. 2015). Understanding the origin of jerks is also important for improving time-dependent models of the geomagnetic field and for the strictly practical purpose of forecasting its future behavior, for example, as used in navigation and orientation.

Summary

In this chapter, we have described the global mapping of the geomagnetic field for the 400+ year period during which direct field observations have been available. The mapping technique involving the fitting of spherical harmonic models

Geomagnetic Field, Global Pattern, Fig. 11 Geomagnetic jerks as seen in the secular variation of the east component of the geomagnetic field observed at European observatories. Times of jerks are shown by arrows

is described, and maps of the various components of the magnetic field are provided for 1600, 1950 and the present day. The geomagnetic field is constantly changing on a range of temporal and spatial scales, and these changes provide scientists with important information about processes deep inside the Earth.

Geomagnetic Field, IGRF

Aude Chambodut

Institut de Physique du Globe de Strasbourg, Université de Strasbourg/Ecole et Observatoire des Sciences de la Terre, CNRS, Strasbourg Cédex, France

Definition

The International Geomagnetic Reference Field (IGRF) is a series of mathematical models of the Earth's main field and its annual rate of change (secular variation).

Each generation of the IGRF comprises three constituent models:

1. The IGRF model that is a prediction of the state of the main field at an epoch t (considering that the epoch of IGRF model elaboration is approximately between $[t - 3 \text{ years}]$ and $[t - 1 \text{ year}]$).
2. The secular variation model that is also a prediction of the annual variation rate of the main field between epoch t and $(t + 5 \text{ years})$.
3. The Definitive Geomagnetic Reference Field model (DGRF), which is the revision of the previous generation IGRF model 5 years before the epoch $(t - 5 \text{ years})$.

The constituent models are designated provisional or definitive. Once a constituent model is designated definitive, it is not revised in subsequent generations of the IGRF.

Datasets

In Table 1, the periodicity of IGRF's elaboration varies with time. In addition, upgrades are regularly incorporated. For example, the truncation degree/order of the main field spherical harmonic analysis was extended from 10 up to 13 after 1995 (IAGA, Division V, Working Group 8 et al. 2003). Similarly, the precision of the coefficients was extended from 1 nT to 0.1 nT after 1995 (IAGA, Division V, Working Group 8 et al. 2003), and then to 0.01 nT after 2000 (IAGA, Working Group V-MOD et al. 2010, 2015, 2020).

These two changes were made possible by technological advances. Indeed, before 1979, only near-surface data (permanent observatories, repeat stations, land, airborne, and marine surveys; see ► “Geomagnetic Field, Measurement Techniques” and ► “Magnetic Methods, Airborne”) were used (Peddie 1983; Zmuda 1971), and consequently, the spatial distribution of data over the globe remained poor. The International Decade of Geopotential Field Research allowed modelers to take advantage of the excellent spatial coverage and high quality of measurements made by near-polar satellites (see ► “Magnetic Methods, Principles”). The POGO satellites (1965–1971), Magsat (1979–1980), POGS (1990–1993), Oersted (1999–2014), SAC-C (2000–2013), and CHAMP (2000–2010) have all been utilized in the production of the IGRF.

Today, data from permanent magnetic observatories are still the most important source of information about time-varying fields, especially for secular variation constituent models (see ► “Geomagnetic Field, Secular Variation”), while magnetic satellite missions, as the Swarm constellation (2013–), allow the acquisition of homogeneously distributed data over the entire globe during a short period of time (as compared to magnetic observatories time series). The two datasets remain highly complementary.

Basic Mathematical Expression

Each mathematical model consists in a set of coefficients, called Gauss coefficients, associated with solid spherical harmonic functions.

Indeed, in source-free regions (the spherical shell bounded by the Earth's surface and the base of the ionosphere at an altitude around 100 km), the main field, generated by fluid motions in the Earth's electrically conducting liquid outer core, may be expressed as the negative gradient of a scalar potential V , which is represented by a truncated (up to degree N) series expansion (see ► “Geomagnetic Field, Theory”):

$$V(r, \theta, \phi) = R \sum_{n=1}^N \left(\frac{R}{r}\right)^{n+1} \sum_{m=0}^n (g_n^m \cos(m\phi) + h_n^m \sin(m\phi)) P_n^m(\theta)$$

where r , θ , and ϕ are geocentric coordinates according to a reference coordinate system.

r is the distance from the center of the Earth, θ is the colatitude (i.e., $90^\circ - \text{latitude}$), and ϕ is the longitude, R is a reference radius (Earth mean radius) set to 6371.2 km; g_n^m and h_n^m are the Gauss internal coefficients, and $P_n^m(\theta)$ are the Schmidt quasi-normalized associated Legendre function of degree n and order m .

The IGRF coefficients are time dependent. In the series of IGRF mathematical models, the variations are assumed to be linear on 5-year intervals. For the upcoming 5-year epoch, the rate of change is given by predictive secular variation coefficients (see ► “Geomagnetic Field, Secular Variation”).

IGRF Evolving

One of the first suggestions to develop an International Geomagnetic Reference Field model was made in 1954 at the International Association of Geomagnetism and Aeronomy (IAGA) Scientific General Assembly in Toronto. The aim in developing such reference models was to have a common basis for calculating the main geomagnetic field in order to homogenize the results of academical/fundamental studies (on fields as diverse as the crustal and external fields) and to provide the industrial world (Meyers and Davis 1990) with a well-identified description of the Earth's core magnetic field.

Thus, an internationally coordinated effort was carried out under the aegis of IAGA relying on the cooperation between magnetic field modelers, institutes, and agencies responsible for collecting and publishing geomagnetic field data.

Since 1969, date of the first adoption of an IGRF (IGRF-1 valid for 1955–1975), the IGRF has evolved into a series of mathematical models of the Earth's main field (Langel 1987) and its annual rate of change at 5-year intervals covering the period 1900–2025 (Table 1).

Geomagnetic Field, IGRF, Table 1 Summary of IGRF history

Full name	Short name	Valid for	Definitive for
IGRF 13th generation	IGRF-13	1900–2025	1945–2015
IGRF 12th generation (revised 2019)	IGRF-12	1900–2020	1945–2010
IGRF 11th generation (revised 2009)	IGRF-11	1900–2015	1945–2005
IGRF 10th generation (revised 2004)	IGRF-10	1900–2010	1945–2000
IGRF 9th generation (revised 2003)	IGRF-9	1900–2005	1945–2000
IGRF 8th generation (revised 1999)	IGRF-8	1900–2005	1945–1990
IGRF 7th generation (revised 1995)	IGRF-7	1900–2000	1945–1990
IGRF 6th generation (revised 1991)	IGRF-6	1945–1995	1945–1985
IGRF 5th generation (revised 1987)	IGRF-5	1945–1990	1945–1980
IGRF 4th generation (revised 1985)	IGRF-4	1945–1990	1965–1980
IGRF 3rd generation (revised 1981)	IGRF-3	1965–1985	1965–1975
IGRF 2nd generation (revised 1975)	IGRF-2	1955–1980	–
IGRF 1st generation (revised 1969)	IGRF-1	1955–1975	–

New candidate models are carefully produced and widely documented as are their evaluation procedures. The final decision is made by the IAGA Working Group-V Mod. Most of the time, the elected DGRF and IGRF models of the current generation are derived by taking means (sometimes weighted) of the coefficients of selected candidate models. Indeed, one particular selected candidate model cannot be chosen preferably to another as the various datasets, selection criteria of the data, applied corrections, and even modeling methods have their own strengths and weaknesses. The robustness of IGRF lies in the fact that even if there are significant differences between the candidate models in every part of the development chain (datasets, data selections, algorithms, and regularizations), the results are fairly consistent at the end.

General Information about the IGRF and coefficients are available at: <http://www.ngdc.noaa.gov/IAGA/vmod/igrf.html>.

Additional figures and programs to compute the field components for a specific location and time are available at: <http://wdc.kugi.kyoto-u.ac.jp/igrf/index.html> and http://www.geomag.bgs.ac.uk/data_service/models_compass/igrf_form.shtml.

Summary or Conclusions

The IGRF model is the product of a collaborative effort between magnetic field modelers and the institutes involved in collecting and disseminating magnetic field data from

ground observatories and surveys around the world as well as from satellites. IGRF provides a description of the Earth's internal magnetic field.

The IGRF model is a widely used common reference in many academic (from solid earth to space weather) and applied (navigation, localization, communication, etc.) scientific fields.

Introduction

At any point in space, the magnetic field is a vector quantity, characterized by a direction associated with a field strength.

A complete representation of the geomagnetic field needs not only the value of its intensity, but also its direction. Continuous monitoring, modeling, and interpretation of the geomagnetic field are the prerequisites to understand our magnetic Planet. Based on geomagnetic models (► [“Geomagnetic Field, Global Pattern”](#), S. Macmillan), covering very short to longer temporal scales, it makes it possible to understand core dynamics (► [“Core Dynamo”](#), U. Christensen), lithospheric magnetic signals (► [“Magnetic Anomaly Map, Global”](#), H. Kumar; ► [“Magnetic Anomalies: Interpretation”](#), E. Thebaud), and the geomagnetic environment. This represents an important challenge in understanding the System Earth. Clearly, geomagnetic measurements from ground and space represent the main ingredient in modeling and understanding the Earth’s magnetic field (e.g., Manda and Purucker 2018; ► [“Geomagnetic Field, IGRF”](#), A. Chambodut). Furthermore, magnetic measurements are also used in connection with different geophysical surveys (ground and/or airborne) for detecting mineralization and/or geological and tectonic structures. They are also used to detect archaeological sites, shipwrecks, and other buried or submerged objects. Moreover, magnetic techniques are used at drilling sites for navigating well-bores, or in monitoring the geomagnetically induced currents which can result in damage to transformers, a potentially major expense to power companies. Finally, prediction of space weather is crucial considering its potential impact on man-made technologies on Earth and in space (satellites, electricity power grids, pipelines, radio and telephone communications, geophysical exploration, etc.).

Two types of measurements are needed to characterize the geomagnetic field: scalar and vector. Scalar measurements are based on the transformation of a frequency – a very accurate measurement – into intensity of the magnetic field. In the spectral domain, the measurement is indeed the location of the center of the spectral line. In a proton magnetometer, protons in a liquid (such as water or kerosene) are first polarized; when the polarizing field is switched off, the protons precess around the magnetic field direction with a frequency which is proportional to the magnetic field intensity. Overhauser magnetometers are typically installed at magnetic observatories, having been also used for some other ground observations or on board of the Ørsted and CHAMP magnetic satellites.

In contrast, vector measurements made with a fluxgate magnetometer are based on the nonlinearity of the magnetization of soft magnetic materials. The very sensitive part of this instrument is an easily saturable core made of a material with high permeability. This core is wrapped by two windings: an excitation coil and a pick-up coil. An alternating excitation current is passed through the excitation coil, driving the core through an alternating cycle of magnetic saturation. This changing field induces an electrical current in the pick-up coil, and this output current can be accurately

measured. The fluxgate magnetometers are subject to an instrument drift. To minimize this drift in the final data, different approaches are used to calibrate the fluxgate magnetometers used for ground and satellite observations.

The instruments used to measure the magnetic field on ground or in space are based on the same physical concepts, and they are basically the same. Of course, for space missions constraints are imposed by weight and consuming energy. More details on magnetometers used in ground-based observations and newly studies on absolute calibration of a vector magnetometers are given in section [“Earth’s Surface Magnetic Field Measurements”](#). Measurements carried out by satellite missions are presented in section [“Near-Earth Magnetic Field Measurements”](#). Finally, in section [“Summary”](#) we offer a perspective on promising avenues in measuring the magnetic field.

Earth’s Surface Magnetic Field Measurements

General Observatory Setting

Historically, magnetic observatories were established to monitor the secular change of the Earth’s magnetic field, and this remains one of their major functions (► [“Geomagnetic Field, Secular Variation”](#), M. Korte). This, generally involves *absolute measurements* that are sufficient in number to monitor instrumental drift of fluxgate magnetometers giving *variation measurements* of the three field components (X – North, Y – East and Z – vertical), in arbitrary units (► [“Magnetometers”](#), I. Hrvoic).

Absolute measurements. A scalar measurement of the field intensity obtained commonly by a proton magnetometer is absolute: as noticed before it depends only upon our knowledge of a physical constant and a measurement of frequency. The measurements achieved with such an instrument have a great accuracy (in excess of 10 ppm). Fig. 1a shows an Overhauser magnetometer.

Scalar magnetometers make measurements of the strength of the magnetic field only and provide no information about its direction. It is also possible to make an absolute measurement of direction of the geomagnetic field, by measuring the angle I (*inclination*) with respect to the horizontal plane, and the angle D (*declination*) in the horizontal plane between the magnetic North and true North (the last one determined by reference to a fixed mark of known azimuth, obtained astronomically or by using a gyro). A fluxgate-theodolite (DI-flux), as shown in Fig. 1b, used commonly to measure D and I , requires manual operation. The DI-flux consists of a nonmagnetic theodolite and a single-axis fluxgate sensor mounted on top of a telescope. The DI-flux is considered to be an absolute instrument, which means that the angles measured by the instrument do not deviate from the true values D and I . This is achieved by using an observation procedure that eliminates unknown parameters such as sensor offset,

Geomagnetic Field, Measurement Techniques,

Fig. 1 Geomagnetic observatory sensor package: proton magnetometer (a), fluxgate magnetometer (b), theodolite with fluxgate coupled to the telescope (c)

collimation angles, and theodolite errors. For example, collimation errors between the fluxgate sensor and the optical axis of the theodolite, and within the theodolite, are minimized by taking readings from four telescope positions. With the fluxgate sensor operating in the null-field mode, the stability and sensitivity of the sensor and its electronics are maximized. In a land-based observatory, such absolute measurements are typically performed once/twice a week, manually, and are used to monitor the drift of the fluxgate variometers.

Over the last decade, high temporal and field resolution data are requested from observatories to complement the magnetic satellite magnetic. One option comes from the dIdD (delta Inclination/delta Declination) magnetometers recording the field components by using a coil system around a proton magnetometer (e.g., Csontos et al. 2012). A second type of instruments aiming to provide continuous (quasi-) absolute recordings are the optically pumped magnetometers, where the sensor contains a gas, helium, or an alkali vapor such as cesium, rubidium, or potassium. These instruments have higher measurement rates and lower noise than Overhauser magnetometers, being suitable for fast moving platforms, as airplanes and satellites.

Variation measurements. A vector measurement is made with a fluxgate magnetometer which operates with minimal manual intervention. These instruments require temperature-controlled environments and installation on extremely stable platforms (however, some modern systems are suspended and therefore compensate for platform tilt). Even with these precautions they can still be drifting subject arising from sources both within the instrument (temperature effects) and also the stability of the instrument mounting. Because these measurements are not absolute, they are referred to as variation measurements, they have to be calibrated against standard instruments, and then the instruments are known as *variometers*. One of the most widely used variometers is the FGE fluxgate (see Fig. 1c). The sensor unit consists of three orthogonally mounted sensors on a marble cube. In order to improve long-term stability, these sensors have compensation coils wound on quartz tubes, resulting in a sensor drift of only a few nT per year. The marble cube is suspended by two strips of crossed phosphor-bronze working as a cardanic suspension to compensate for pillar tilting that might cause baseline drift. The box containing the electronics is almost magnetic free and is placed several meters from the sensor to further

minimize its effect on the readings. The magnitude and directional response of these instruments needs to be calibrated against accurately known sources.

All modern land-based magnetic observatories use similar instrumentation and process the data in a comparable way to produce similar data products. For a full description, see the INTERMAGNET web site (<http://www.intermagnet.org>; accessed June 2020). The fundamental measurements recorded are averaged one-minute values of the vector components and of scalar intensity. From the one-minute data, hourly, daily, monthly, and annual mean values are produced.

Due to developments in observatory instrumentation and data acquisition, filtered one-second data product have become available through the INTERMAGNET network. Since 2014 definitive one-second data are provided to the user community. The minimum standard of magnetometer performance is actually given by high stability and low noise, good linearity, high resolution – <0.01 nT, and fast dataloggers with an accuracy of the time-stamp – within 0.01 s, and sharp filtering. All the parameters describing the specifications of a complete observatory system for a one-second vector data are resumed in Turbitt et al. (2013).

Finally, let us note that data processing consists in a weekly determination of baseline values from absolute measurements. The processing has to include the determination of all systematic errors, and the quality of measurements depends strongly on the experience and accuracy of the observer. Because of this subjective parameter in the final data products and because regular absolute measurements lack in remote areas, several attempts have been made to operate absolute vector field instruments automatically. Already, some 50 years ago, Alldredge planned an automatic standard magnetic observatory (Alldredge and Saldukas 1964), that is, a device providing at each time the absolute values of the geomagnetic field (without extra independent absolute measurements, at least for a long enough time span). This idea has remained in the geomagnetism community and, over the last years, attempts have been made to automate a DI-theodolite (van Loo and Rasson 2007), or to build a device which can perform discrete absolute measurements automatically (Auster et al. 2007). One important issue remains the orientation problem for an automatic magnetic observatory, and here we briefly summarize it.

Absolute Calibration of a Vector Magnetometers

Gravrand et al. (2009) addressed the question of the internal calibration of a vector (or tri-axial) magnetometer, such as the ^4He pumped magnetometer built by the Laboratoire d'électronique et de technique de l'information (LETI/CEA), or the Oersted space mission fluxgate magnetometer, built by the Institute for automation of the Danish Technical University (DTU). The problem of the internal calibration is to determine the six (^4He magnetometer) or nine (fluxgate

magnetometer) intrinsic parameters: the three scale values (one for each modulation coil physical axis in the ^4He case, or each fluxgate sensor axis in the fluxgate case), the three angles between the three physical axis in both cases, and the three offset values in the case of the fluxgate variometer.

The calibration problem can be solved by rotating in space the triaxial magnetometer while making simultaneously absolute intensity measurements with a proton or optical pumping magnetometer (Olsen et al. 2003), and it is essentially linear (Gravrand et al. 2009). The calibration algorithm was developed for ground operation and extended to in flight calibration. This internal calibration is not enough when installing somewhere a genuine automatic magnetic observatory. Gravrand et al. (2009) noted that an absolute calibration should not be too difficult in a place where standard absolute measurements can be performed. A quite practical interest is linked to this statement, which was addressed by Khokhlov et al. (2013), who showed that the above statement is both valid and invalid, depending on the objective, and demonstrated that only the determination of the scale factors provided by the internal calibration process are of interest for the absolute calibration. Due to a lack of space, we do not detail this algorithm here and the interested reader can refer to Khokhlov et al. (2013).

Near-Earth Magnetic Field Measurements

High accuracy and precision measurements of the near-Earth geomagnetic field from space began with NASA's MAGSAT satellite that flew for 6 months from 1979 to 1980. This was followed in the first decade of the twenty-first century by the Ørsted ([https://en.wikipedia.org/wiki/Ørsted_\(satellite\)](https://en.wikipedia.org/wiki/Ørsted_(satellite)); accessed June 2020), CHAMP (<http://www.gfz-potsdam.de/champ/>; accessed June 2020), and SAC-C magnetic field satellites. These missions have been very important for modeling and a better understanding of the geomagnetic field and its spatial and temporal variations. The huge step in measuring the magnetic field from space has arrived with the launch of the Swarm mission.

Swarm (http://www.esa.int/Our_Activities/Observing_the_Earth/Swarm; accessed June 2020), the 3-satellite ESA constellation, is the most current and most advanced geomagnetic observatory in space. All three satellites are identical and the setting of the magnetic instruments on the boom is given in Fig. 2. One of the novelties of the mission is not only the constellation concept, but also the new absolute scalar magnetometer, an optically pumped ^4He magnetometer, which provides absolute scalar measurements of the magnetic field with high accuracy and stability for the calibration of the vector field magnetometer (Leger et al. 2009). The mission was designed to derive the first global representation of the geomagnetic field variations on time-scales from an hour to several years, addressing the crucial problem of source

Geomagnetic Field, Measurement Techniques, Fig. 2 The Swarm satellite. The main magnetic instruments are installed on the 4-m boom, the absolute scalar magnetometer (at the very end) and the vector magnetometer, and the three star trackers (halfway along the boom). (Credit ESA)

separation. The three Swarm satellites are identical, and the constellation consists of two satellites (A and C) flying almost side-by-side at an altitude close to 460 km (April 2016), longitude separation of 1.4° and on circular and almost polar orbits with an inclination of 87.4° . The third satellite (B) flies higher, close to 510 km (April 2016), on a more polar orbit (inclination of 87.8°) and is progressively separated in LT with respect to A and C.

On Swarm satellites, the magnetic instruments are mounted on the boom, which accounts for almost half the length of the satellite and trails at the back. This solution is needed as the front surface is used for the electric field instrument to collect and measure the speed and direction of incident ions along the orbital path. The optical bench holding the vector magnetometer and the three star trackers is mounted halfway along the boom. The vector field magnetometer is the main instrument, providing high-precision measurements of the magnitude and direction of the magnetic vector field. This latest generation of instruments was developed and manufactured at the Technical University of Denmark. The absolute scalar magnetometer measures the strength of the magnetic field to greater accuracy than any other magnetometer. It was developed and manufactured by LETI/CEA and provides scalar measurements of the magnetic field to calibrate the vector field magnetometer.

Swarm magnetometers measure a superposition of magnetic fields produced by a number of different sources: core, lithosphere, ionosphere, and magnetosphere. Note that contributions due to external sources depend largely on latitude, LT, and solar activity, and that other satellites have the capability of making highly precise and accurate magnetic field measurements with fluxgate magnetometers within the magnetosphere or ionosphere. Examples include Cluster (<http://sci.esa.int/cluster/>; accessed June 2020), MMS (<http://mms.gsfc.nasa.gov>; accessed June 2020), and the Van Allen Probes (http://www.nasa.gov/mission_pages/rbsp/mission/; accessed June 2020). These can augment the results of the Swarm mission in the distant magnetosphere and illuminate the process of magnetic reconnection for example.

Summary

Here, we concentrate primarily, but not exclusively, on geomagnetic instruments and techniques used in a magnetic observatory settings or in a near-Earth magnetic satellites. We have briefly described the basic instruments, their mode of operation, their relative and/or absolute accuracy, and the related sources of error. It is more likely that some instrumental advances will be made towards the aim to stabilize vector magnetometers. Advances will be made in power reduction, data storage and telemetry with the goals of increased automation and cutting costs. The coming age of the automated absolute instruments makes it possible to consider once again the possibility of a true underwater observatory. The future needs of the scientific and commercial users will include ground-based and space measurements. Increasing resolution and timing accuracy will be crucial. However, to achieve these requirements will demand more efforts from instrument makers and spacecraft designers.

The Swarm mission may continue to operate until the 2030s, when the lower two satellites will re-enter the atmosphere, leaving only the higher altitude satellite. In order to be assured of high-quality geomagnetic field data in the future, it is important to develop concepts for future missions now. One possibility is the use of one or more CubeSats with scalar ^4He magnetometers, a concept under development in France. This implies new instrument developments, including the need to miniaturize the optically pumped ^4He magnetometer. Diamond vector magnetometry, using nitrogen vacancy centers in diamond, is another promising class of absolute scalar and vector magnetometers that may see use in observatories and satellite missions of the future.

Geomagnetic Field, Polarity Reversals

Carlo Laj
Laboratoire des Sciences du Climat, Unité mixte
CEA-CNRS-UVSQ, Gif-sur-Yvette, France

Introduction: The Discovery of Geomagnetic Reversals

Bernard Brunhes (1906) was the first to measure magnetization directions in rocks that were approximately antiparallel to the present Earth's field. Brunhes (1906) recorded

magnetizations in baked sedimentary rocks that were aligned with reverse magnetization directions in overlying Miocene lavas from central France (Puy de Dome). In so doing, Brunhes (1906) made first use of a field test for primary thermal remanent magnetization (TRM) that is now referred to as the “baked contact” test. Matuyama (1929) was the first to attribute reverse magnetizations in (volcanic) rocks from Japan and China to reversal of geomagnetic polarity, and to differentiate mainly Pleistocene lavas from mainly Pliocene lavas based on the polarity of the magnetization. In this respect, Matuyama (1929) was the first person to use the sequence of geomagnetic reversals as a means of ordering rock sequences.

The reality of geomagnetic reversals was then progressively established with the studies of Hospers (1951, 1953) in Iceland, and Roche (1950, 1951, 1956) in the Massif Central of France. The work of Hospers on Icelandic lavas was augmented by Rutten and Wensink (1960) and Wensink (1966) who subdivided Pliocene-Pleistocene lavas in Iceland into three polarity zones from young to old: N-R-N. Magnetic remanence measurements on basaltic lavas combined with K/Ar dating, pioneered by Cox et al. (1963) and McDougall and Tarling (1963a, b, 1964), resulted in the beginning of development of the modern geomagnetic polarity timescale (GPTS). These studies, and those that followed in the mid-1960s, established that rocks of the same age carry the same magnetization polarity, at least for the last few million years. The basalt sampling sites were scattered over the globe. Polarity zones were linked by their K/Ar ages, and were usually not in stratigraphic superposition. Doell and Dalrymple (1966) designated the long intervals of geomagnetic polarity of the last 5 Myrs as magnetic epochs, and named them after pioneers of geomagnetism (Brunhes, Matuyama, Gauss, and Gilbert).

Then, the discovery of marine magnetic anomalies confirmed seafloor spreading (Vine and Matthews 1963), and the GPTS was extended to older times (Vine 1966; Heirtzler et al. 1968; Lowrie and Alvarez 1981). Since then, the succession of polarity intervals has been extensively studied and used to construct magnetostratigraphic timescales linking biostratigraphies, isotope stratigraphies, and absolute ages (see Opdyke and Channell 1996, “Magnetic stratigraphy”, for a review).

The Geomagnetic Polarity Timescale

The fit of the land-derived polarity timescale, from paleomagnetic and K/Ar studies of exposed basalts, with the polarity record emerging from marine magnetic anomalies (MMA) (Vine and Matthews 1963; Vine 1966; Pitman and Heirtzler 1966; Heirtzler et al. 1968) resulted in a convincing argument for synchronous global geomagnetic polarity reversals, thereby attributing them to the main axial dipole. This intense research effort has culminated with the work of Cande and

Geomagnetic Field, Polarity Reversals, Fig. 1

The geomagnetic polarity timescale for the last 160 My. Numbers indicate the marine magnetic anomalies

Kent (1995) based on the Marine Magnetic Anomalies record, using the South Atlantic as the fundamental template with inserts from faster spreading centers in the Indian and Pacific oceans. Cande and Kent (1995) adopted the astrochronological age estimates for the Pliocene-Pleistocene polarity reversals and fixed the age tie-point at the Cretaceous-Tertiary boundary at 65 Ma (Fig. 1).

The Changing Frequency over Time and the Duration of Geomagnetic Reversals

Examination of the geomagnetic polarity timescale reveals some of the major characteristics of geomagnetic reversals. First, a clear characteristic is the widely different duration of periods of stable polarity separating geomagnetic reversals. Long periods of time during which there were no reversals have been clearly identified, such as the Cretaceous Long Normal Chron (also called the Cretaceous Superchron,

about 118–183 million years ago) or the Kiaman Superchron, which lasted approximately from the late Carboniferous to the end of the Permian.

The frequency of reversals decreased prior to the Cretaceous Superchron, and slowly increased over the 80 million years from the end of this Superchron to the present. It has been suggested (Mazaud et al. 1983; Mazaud and Laj 1991) that in this last period the frequency does not increase randomly but presents a dominant frequency corresponding to a period of approximately 15 million years. This suggestion has, however, been received with some skepticism (McFadden 1987). The most recent analyses seem to converge toward a nonstationary Poisson process or at least a gamma process with k only slightly greater than 1 (Lowrie and Kent 2004).

Another characteristic, revealed from the very beginning by the studies of reversals, is that the Earth's magnetic field strength drops to low levels during polarity reversals. There has been some debate on whether this drop is symmetrical or

not on each side of the reversal. Valet and Meynadier (1993) suggested that the dipole intensity slowly decreases over a long period of time preceding a reversal and rapidly increases immediately after (the so-called sawtooth hypothesis). These authors also suggested that there is a positive correlation between the magnitude of the increase in intensity and the length of the subsequent polarity interval.

The sawtooth pattern, however, is not present in many sedimentary records (Tauxe and Shackleton 1994; Tauxe and Hartl 1997; Laj et al. 1996; Channell and Kleiven 2000; Channell et al. 2009). Interpretations of the sawtooth pattern, other than true geomagnetic behavior, have been given, either assuming sedimentary postdepositional artifacts (Mazaud 1996) or the presence of a cumulative viscous component not removed by alternating field demagnetization (Kok and Tauxe 1996a, b). Moreover, McFadden and Merrill (1998) have strongly questioned the suggestion that the duration of polarity intervals could be determined by the amplitude of the field recovery after the reversal. The fast recovery of the field intensity after the reversal does not appear either in a recent reconstruction of the Brunhes–Matuyama transition, based on four independent records, where the pre- and posttransitional intensity records appear symmetric about the reversal (Leonhardt and Fabian 2007). In summary, the experimental evidence for the sawtooth hypothesis is controversial.

Also clearly apparent from the geomagnetic polarity time-scale is the extremely short duration of polarity reversals compared to periods of stable polarity. The time it takes for the reversal to happen has been roughly estimated from the early works (Harrison and Somayajulu 1966; Cox et al. 1963, 1964; Cox 1969) to be between 10^3 and 10^4 years, with some estimates up to 28,000 years. In a recent article, Clement (2004) presents an analysis of available sedimentary records and shows that these records yield an average estimate of 7000 years for the duration of a reversal. Moreover, the duration varies with site latitude, with a shorter duration observed at low-latitude sites. This short duration has been one of the most delicate factors to overcome in studying the detailed structure of reversals.

The Morphology of Geomagnetic Reversals

Because of its importance to dynamo theory, the morphology of the geomagnetic field during reversals and whether or not it displays statistical asymmetries has been a subject of continuous research for many years. Records of geomagnetic field changes during a polarity transition have, however, been difficult to obtain, not only because of their short duration mentioned above, but also because the magnetizations of the rocks is weak due to the low intensity of the transitional field. It is only with the advent of sensitive magnetometers that the number of published transitional records has rapidly increased.

In probably the most famous of the early records, Hillhouse and Cox (1976) showed that the Virtual Geomagnetic Pole (VGP) (The Virtual Geomagnetic Pole is defined as the pole of the geocentered axial dipolar field that would give the observed direction of the field at the observation site. If the VGPs observed at several sites at a given time coincide, then the field has a dipolar structure.) path for the Brunhes–Matuyama transition recorded in sediments from Lake Tecopa (California) was different from the one previously obtained by Niitsuma (1971) from the Boso Peninsula in Japan, thereby providing evidence that the transitional field is not dipolar. Although in a more recent article Valet et al. (1988a) showed that the AF demagnetization used by Hillhouse and Cox (1976) did not completely remove a strong overprint, the conclusion that the transitional field was not dipolar was maintained.

Another famous record was obtained from a Miocene lava sequence at the Steens Mountain (Mankinen et al. 1985; Prévot et al. 1985). The record displays several phases with large swings, one of which occurring at the extremely rapid rate of $50 \pm 21^\circ$ per year, while the intensity change was $6700 \pm 2700 \mu\text{T}$ per year, about 10–50 times larger than the maximum rate of change observed for the non-dipole field in historical records. These amazing rates of change are still a matter of discussion among geophysicists.

Other transitional records were obtained from lava sequences in French Polynesia (Roperch and Chauvin 1987; Roperch and Duncan 1990; Chauvin et al. 1990). These records appear to indicate that a zonal field dominates the beginning of the transition, then non-dipolar terms emerge without any preferred axi-symmetry, consistent with an earlier suggestion by Hoffman (1982).

Transitional records from sequences of relatively high accumulation rate marls in Western Crete (Greece), were reported in a series of papers by Valet and Laj (1981, 1984) and by Valet et al. (1983, 1986, 1988b). The results from multiple records indicated that the reversal process observed for four sequential transitions remained unchanged for about 1.3 Ma. In one record, obtained from a particularly high sedimentation rate section, fast directional fluctuations, reminiscent of the Steens Mountain record, were observed whose amplitude significantly increases during the transition. Slight smoothing of the data reveals that almost periodic fluctuations occurred on a longer timescale during the transition (Valet et al. 1986).

Two landmark papers were published almost simultaneously and independently in 1991. Clement (1991) examined records of the Brunhes–Matuyama transition obtained from the northern, equatorial, and southern latitudes in the Atlantic sector. The VGP paths from the mid-latitudes in the northern and southern hemispheres are nearly coincident and extend over the Americas. Paths from the equatorial site track almost antipodal to the other paths. These results suggest that during the reversal VGPs tend to fall along two longitudinal bands.

Geomagnetic Field, Polarity Reversals, Fig. 2

The compilation of sedimentary records for the last 12 My (Laj et al. 1991) indicating the existence of preferred longitudinal bands for transitional VGPs. The blue shaded zones are characterized by fast seismic velocities in the lower mantle

From a compilation of all the available sedimentary records from several sites and spanning about 12 million years, Laj et al. (1991) suggested that reversals and excursions exhibit geometric regularity: the VGP paths of these transitions tend to fall along either American or Asian-Australian longitudes, that is, the same as for the Brunhes-Matuyama reversal (Fig. 2). As remarked by the authors a persistent geometry over 12 Ma has important geomagnetic consequences: since the duration between transitions is longer than both the core's convective and magnetic diffusion time-scales, the most plausible mechanism by which the core could retain a memory of previous transitions, particularly preferred longitudinal bands, is through some form of core-mantle coupling. This argument was reinforced by Laj et al. (1991) who noted the apparent correlation between preferred longitudes and lower mantle seismic velocity variations, possibly arising from thermal heterogeneities.

The suggestion of preferred longitudinal bands for transitional VGPs has, however, been met with some skepticism, some authors questioning the adequacy of the geographical distribution of the sites (Valet et al. 1992), or the reliability of transitional records from sediments (Langereis et al. 1992; Barton and McFadden 1996). Statistical analyses of the distribution of path have not given a clear answer (Weeks et al. 1992; McFadden et al. 1993; Quidelleur and Valet 1994). An initial analysis of transitional records from lavas (which are devoid of many of the problems of sedimentary magnetizations) appeared to indicate that transitional VGPs are statistically axi-symmetric (Prévot and Camps 1993). However, a more recent analysis by Love (1998, 2000) using a mathematical approach in which the records are normalized taking into account differences in recording density of the paleomagnetic directions, has concluded that the volcanic transitional VGPs indeed show a significant tendency to fall along American and Asian-Australian longitudes, consistent with the sedimentary data. The existence of preferred longitudinal bands for transitional VGPs must, therefore, be considered as a realistic suggestion.

Alongside with the observations of records of geomagnetic reversals, phenomenological models have been developed to account for at least the main characteristics of the records. As early as 1976, Hillhouse and Cox (1976) suggested that if the usual non-dipole drift remained unchanged during the reversal, then one should observe large longitudinal swings in the reversal PGV paths. As this was not observed, these authors proposed that an invariant component dominates the field when the usual dipole has vanished (the so-called standing field hypothesis). Subsequently, Hoffman and Fuller (1978) and Hoffman (1979) proposed a model in which reversals originate in particular regions of the core and progressively extend to other regions (the so-called flooding model). None of these models was, however, capable of predicting VGP paths from particular sites on the Earth.

A significant step forward has been made recently, with the development by Leonhardt and Fabian (2007) of a Bayesian inversion method devised to reconstruct the spherical harmonic contents of the geomagnetic field during a reversal from paleomagnetic data. The validity of this inversion technique is proven, in particular, by iteratively combining four geographically distributed high quality paleomagnetic records of the Brunhes-Matuyama reversal into a single scenario without assuming an a priori common age model. The obtained results successfully describe most independent Brunhes-Matuyama transitional records.

Leonhardt and Fabian (2007) were able to discuss many questions about the transitional field, which had been controversially discussed (see, e.g., Merrill et al. (1996)) so far: primarily the question of contribution of dipole versus non-dipole fields during the reversal process. The results of their modeling indicates a strong increase of non-dipolar energy a few kyrs before the reversal. The non-dipole energy prevails on the dipole some 5 kyrs before the dipole minimum, after which both the non-dipole and dipolar energies decrease. Following the minimum in dipolar energy, the non-dipolar energy drops further, while the dipolar energy increases first sharply then progressively recovers (Fig. 3a). The model also

Geomagnetic Field, Polarity Reversals, Fig. 3 (a) Evolution of the dipole and non-dipole energies during the Matuyama–Brunhes polarity transition. (b) Evolution of the dipole and nondipole energies during the Laschamp excursion

shows that, during the reversal, the inverse flux penetrates the tangent cylinder (the imaginary cylinder aligned with the Earth's rotation axis and tangent to the inner core).

Dynamo Mechanisms and Reversals

For many years, scientific opinion has been divided on what causes geomagnetic reversals. Initial suggestions have been made that geomagnetic reversals are not due to spontaneous processes in the Earth's dynamo, but rather that they are triggered by external factors (such as arrival of continental slabs near the core-mantle boundary as a result of plate tectonics, or even mantle-core shear forces linked to external impacts).

Today, most geophysicists believe that reversals are inherent aspects of the dynamo, which generates the geomagnetic field. Recent developments in numerical dynamo models, which take advantage of modern supercomputers, and also an experiment with a laboratory dynamo, point strongly that this is the only sustainable mechanism. In these models the equations describing the time-dependent thermal, compositional, velocity and magnetic field are solved simultaneously

in the three-dimensional spherical geometry appropriate to the core. There is no a priori prescription for reversals, so, if they happen, they are an intrinsic property of the mechanisms of the geodynamo.

The first of these numerical models aiming to simulate Earth-like characteristics was published by Glatzmaier and Roberts (1995). This three-dimensional, selfconsistent model was able to maintain a magnetic field for over 40,000 years. The model, considers a finitely conducting solid inner core, in agreement with findings by Hollerbach and Jones (1993) that a solid inner core tends to stabilize the geodynamo. Over the period of 40,000 year the model undergoes several polarity excursions and finally a reversal is observed. The model, therefore, shares some similarities with real reversals of the geomagnetic field, and therefore may provide insight into the mechanisms of geomagnetic reversals.

In this respect, Glatzmaier et al. (1999) and Coe et al. (2000) have run numerical simulations of the Glatzmaier–Roberts dynamo using a variety of thermal boundary conditions. The model displays a range of behavior that resembles records of real reversals of the Earth's magnetic field. Reversals occurred during both the homogeneous and tomographic simulation (in this last case the heat flux at the Core-Mantle Boundary is patterned after a seismic velocity model from tomographic investigation of the lower mantle). All reversals appear spontaneously, with no external triggering required. The tomographic model of Glatzmaier et al. (1999) also appears to offer some support for the hypothesis that VGPs during reversals correlate with areas of higher than average heat flux.

The question of how well the geodynamo model represents the Earth's field is of course fundamental. Indeed, if the Earth's values for the radius and the rotation of the core are used, then, owing to computation limitations, viscous diffusivity values at least three to four orders of magnitude larger than those of the Earth must be used. So, while some modelers have argued that the field produced by models should be fairly realistic, other modelers are less confident that the results can be directly extrapolated to the Earth, even at the large scales. In the author's opinion, numerical models have very largely improved our understanding of the mechanisms inherent to the production of the Earth's magnetic field.

Finally, a benchmark experiment showing how magnetic field reversals can be generated without any external triggering in a turbulent conducting field has been obtained recently in a laboratory environment, the so-called VKS experiment (this acronym stands for Von Karman Sodium) (Berhanu et al. (2007)). In 2000 experiments in Riga (Gailitis et al. 2001) and Karlsruhe (Stieglitz and Müller 2001) showed that fluid dynamo could be generated by fluid sodium flows, when a favorable geometry is imposed to the flow. In the more recent VKS experiment, a turbulent flow is produced in a copper cylinder filled with liquid sodium whose flow is created by

Geomagnetic Field, Polarity Reversals, Fig. 4 Evolution of the magnetic field measured inside the flow vessel during the VKS experiment. The main component (red) is the azimuthal one. Note that all components decay to zero at a reversal. The bottom graph shows the evolution of the power driving the flow. (Adapted from Berhanu et al. 2007)

two counter-rotating impellers. When the speed of the impellers exceeds a critical value, the flow spontaneously generates a magnetic field that is self-sustained by the flow itself. This field undergoes large fluctuations, originating from the high level of turbulence. The most spectacular result was observed when the two impellers were counter-rotated at different speeds: in this case the temporal evolution of the field is characterized by a series of erratic reversals of polarity. These reveal remarkable similarities with the Earth's magnetic field, in the sense that the duration of the transitions is very short compared to the periods of stable polarity. In addition, excursions are also present, during which the field decays to very low values before growing again without a change in polarity (Fig. 4). Although similarity to the Earth's magnetic field should not be overstressed, this laboratory experiment clearly shows that reversals can appear spontaneously, as a consequence of the complexity of the fluid flow, without any necessity for an external triggering.

Outlook: The Future of Geomagnetic Reversals

The geomagnetic dipole has decreased in recent historical times at a rate of 5% per century, which is about 10–12 times the rate of free Ohmic decay of the geomagnetic dipole field in the core. Additional evidence for this rapid decrease is the poleward migration of large patches of reverse magnetic field at the core-mantle boundary that have largely contributed to the historical dipole field drop (Olson and Amit 2006). Therefore, this is a very rapid change for the geodynamo, which has led to speculations about the possibility of an impending field reversal (Constable and Korte (2006); Olson and Amit (2006)). Because an intensity drop is also

associated with excursions this second possibility should also be considered.

The inverse model of Leonhardt and Fabian (2007) may allow to have a deeper insight on this scenario. Indeed, when applied to the study of the Laschamp excursion (Leonhardt et al. 2009) the model indicates that both dipolar and non-dipolar energies at the Earth's surface decrease at approximately the same time with similar rates. The dipolar energy reaches its minimum slightly later than the non-dipolar energy. Then, for a brief interval the non-dipolar energy prevails, contrary to the Brunhes–Matuyama reversal discussed above where the non-dipole energy prevails on the dipole some 5 kyrs before the dipole minimum, after which both the non-dipole and dipolar energies decrease (Fig. 3b). The time evolution of the dipole versus non-dipole fields is different for a reversal or an excursion and could, therefore, be an indicator for an incoming reversal or excursion.

At present, however, the non-dipole field energy is about one order of magnitude smaller than the dipolar term. This latter is still larger than the dipole energy calculated before either a reversal or an excursion using the Leonhardt and Fabian approach. So despite the decreasing trend of dipole energy, there is no indication in the present field that would point toward either type of instability. Together with Olson and Amit (2006), Leonhardt et al. (2009) therefore consider that it is not justified to consider the present decrease in dipole energy and an indication of an imminent reversal. We will have to wait some more time to know whether we are heading toward a reversal, an excursion, or whether we are simply undergoing an intensity fluctuation.

Acknowledgments I thank Alain Mazaud for helpful discussions during the writing of the manuscript.

Geomagnetic Field, Secular Variation

Monika Korte

Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, Potsdam, Germany

Definition

The geomagnetic field observed at and above the Earth's surface varies on a broad range of timescales, from less than seconds to millions of years. In general, fast variations with periods less than a year originate from sources external to the Earth. Secular variation is the continuous variation of direction and intensity of the geomagnetic core field, associated to changes of fluid flow in the outer core (see, e.g., Jackson and Finlay 2015 for a detailed review on secular variation). The name originates from the Latin “seculum,” referring to a time interval of about a century. Secular variation describes the velocity of field change or the first temporal derivative of a time series of field observations. The second derivative, or

rate of change of secular variation, is called secular acceleration.

Secular variation consists of mostly nonperiodic, non-predictable field changes. The high-frequency end of the temporal secular variation spectrum is not well-understood. Very rapid variations that might occur in the core are damped and filtered out when passing through the mantle before being observed. The fastest measured secular variation features are named geomagnetic jerks and rapid fluctuations. They are caused by rapid secular acceleration changes and occur on timescales on the order of 1 year (Mandea and Olsen 2009). It is challenging to discriminate between internal and external variations in observational data on these timescales. Long-term external field changes, linked in particular to the approximately 11-year sunspot cycle, are also reflected in any measured time series.

On several thousands to million year timescales, the usually moderate secular variation is interrupted by excursions and complete polarity reversals of the geomagnetic core field (see ► “[Geomagnetic Excursions](#)” and ► “[Geomagnetic Field, Polarity Reversals](#)”). It is unclear whether these should be seen as part of the secular variation spectrum, or whether they have a distinctly different physical mechanism. The maximum possible rates of secular variation are recently debated since rapid high intensity “spikes” have been found in archaeomagnetic data (Shaar et al. 2011; Livermore et al. 2014, Korte and Constable 2018).

Geomagnetic secular variation is not globally uniform. The geomagnetic dipole moment, a measure of the overall global field strength, has been decreasing at a rate of 6% per century since the beginning of systematic magnetic field intensity observations around 1840. The present spatial distribution of intensity secular variation is characterized by large areas of intensity decrease over North America, large parts of the Atlantic and the southern Pacific, and smaller areas of intensity increase over the Indian Ocean, northern Africa, Europe, and Asia (Thébault et al. 2015). Present, historical and paleomagnetic data indicate that secular variation has always been weak in the Pacific compared to the Atlantic hemisphere, which might be a consequence of lateral variations in lower mantle temperature (see, e.g., Gubbins and Gibbons 2004). Higher secular variation in the southern than northern hemisphere characterizes at least the Holocene geomagnetic field evolution (Constable et al. 2016).

Geomagnetic Field, Theory

Friedrich H. Busse

Institute of Physics, University of Bayreuth, Bayreuth, Germany

Definition

Motions of an electrically conducting fluid without a magnetic field may become unstable and develop a magnetic field if the magnetic Reynolds number is sufficiently high. This process is called a dynamo. The magnetic Reynolds number is proportional to the electrical conductivity of the fluid, the amplitude of motion, and the typical scale of motion. The simplest example of a dynamo process is the disk dynamo first considered by Faraday. The exact nature of the motions driving the geodynamo in the liquid iron core of the Earth is still a subject of debate.

Introduction

The forces exerted by magnetized rocks or lodestones have been known to mankind for many centuries before Christ, but

the directivity of the lodestone appears to have been first observed by the Chinese in the first century B.C. It is known that at this time Chinese geomancers used a freely turnable spoon-like lodestone on a polished plate as a compass, not for navigational purposes, but probably for aligning tombs and houses. As navigational instrument the compass was introduced to European sailors by Arabic merchants in the twelfth century A.C. A first systematic experimental study of the forces exerted by lodestones was published by Petrus Peregrinus in 1269. Some of his results are shown in Fig. 1a. More refined experiments were carried out and described in his book *De Magnete* by William Gilbert (1600). He concludes that the Earth itself is a magnet like a lodestone.

In 1839 Carl-Friedrich Gauss introduced the representation in terms of spherical harmonics for the observed geomagnetic field. Through this representation, it became possible to separate the magnetic fields of internal and external origin. The latter, being much smaller than the former and much more variable in time, is caused by ionospheric and magnetospheric currents. Only during magnetic storms can the externally generated magnetic field reach a significant fraction of the total strength of the Earth's magnetic field (see ► “Electromagnetic Pulsations and Magnetic Storms”). Together with Alexander von Humboldt Gauss founded in 1836 the Göttinger Magnetischer Verein (Göttingen Magnetic Union) in order to create a worldwide network of observatories for the measurement of the magnetic field and its

variations in time. Since that time the knowledge about the geomagnetic field and its time dependence has improved continuously (see ► “Geomagnetic Field, Global Pattern”).

The idea that the geomagnetic field originates from the ferromagnetism of the Earth's interior prevailed until the end of the nineteenth century even though the phenomenon of secular variation – known since the seventeenth century – was difficult to reconcile with the hypothesis of remanent magnetism. In early years of the twentieth century, it became clear that the Curie temperature of ferromagnetic material is exceeded within the entire Earth except for the uppermost few tens of kilometers and that the magnetization of the Earth's crust is far too weak to act as a source of geomagnetism. Numerous other hypotheses have been proposed as origin of geomagnetism and rejected (Rikitake 1966) except for the dynamo hypothesis. In the meantime, magnetic fields had been observed on the sun and in 1919 Larmor proposed the dynamo mechanism for the origin of the magnetic field of sunspots.

According to the dynamo hypothesis motions within the outer liquid-iron core of the Earth can amplify a magnetic field from arbitrarily small amplitudes and sustain it at the observed finite strength against Ohmic dissipation. The feasibility of this mechanism in a simply connected region of nearly uniform electrical conductivity appeared to be doubtful for a long time, and the dynamo hypothesis experienced a setback when Cowling (1934) demonstrated that axisymmetric magnetic fields cannot be generated by the dynamo

mechanism. Since the geomagnetic field is axisymmetric in first approximation, Cowling's theorem stimulated the search for alternative mechanisms. It was not until the late 1950s that Backus (1958) and Herzenberg (1958) demonstrated independently that dynamos are indeed possible in spheres of uniform conductivity.

Since that time dynamo theory has developed rapidly and it has become generally accepted that a geodynamo operates in the liquid outer core of the Earth. While in the 1960s and 1970s of the past century analytical models of the geodynamo have prevailed, the strong growth of computer capacities in recent decades has permitted numerical simulations with ever increasing details of convection driven dynamos in Earth's core-like rotating spherical shells. The principles of the dynamo process in such an environment are now reasonably well understood. The remaining uncertainties are caused by an insufficient knowledge of conditions in the Earth's core and lower mantle and the inability to model the dynamo process under the highly turbulent conditions of flow in the outer core.

Before outlining the concepts of dynamo theory, we briefly mention the role of the crustal magnetic field which originates from ferromagnetic remanence of material below its Curie temperature in the lithosphere. When the observed magnetic field is represented in terms of spherical harmonics (see ► [“Geomagnetic Field, IGRF”](#)), it is found that crustal contributions dominate in coefficients of the degree 14 and higher. The crustal contributions to coefficients of lower degrees are still substantial, of course, but they do not exceed those originating from the core in general (see ► [“Magnetic Anomaly Map, Global”](#)). Crustal magnetic fields are often correlated with geological features and may indicate iron ore deposits such as the famous Kursk formation in the Ukraine. Other important crustal magnetic features are the magnetic stripes of the ocean floors extending parallel to the mid-oceanic ridges which represent the most convincing evidence for the concept of plate tectonics (see ► [“Magnetic Anomalies: Interpretation”](#)).

The following sections are devoted to the dynamo theory of geomagnetism and its applications to the Earth's core. We shall start with the simplest dynamo device that converts mechanical energy into magnetic energy and then proceed to the concepts of the geodynamo. The current state of numerical models of the geodynamo will be described in another entry under the heading ► [“Core Dynamo”](#).

Kinematic Dynamo Theory

The simplest description of a dynamo is obtained for a fixed velocity field, that is, when the feedback of the generated magnetic field on the flow through the action of the Lorentz force is neglected. A single equation of magnetic induction

describing the time dependence of the magnetic flux density $\vec{B}$ can be derived from Maxwell's equations in the magneto-hydrodynamic approximation, in which the displacement current is neglected, and from Ohm's law which are given by

$$\begin{aligned} \nabla \cdot \vec{B} &= 0, & \frac{\partial \vec{B}}{\partial t} &= \nabla \times \vec{E}, & \nabla \times \vec{B} &= \mu \vec{j}, \\ \vec{j} &= \sigma (\vec{E} + \vec{v} \times \vec{B}) \end{aligned} \quad (1)$$

where $\vec{B}$ is the magnetic flux density, $\vec{E}$ is the electric field and $\vec{j}$ is the current density. σ , μ and $\vec{v}$ denote the electrical conductivity, the magnetic permeability and the velocity vector, respectively. Ohm's law has been written in the form valid for a moving conductor. Accordingly Eqs. 1 are invariant with respect to a Galilei transformation; in other words, the same Eqs. 1 hold in a system moving with constant velocity $\vec{V}$ with respect to the original system of reference when $\vec{v}$, $\vec{E}$ and $\vec{B}$ obey the relationships

$$\vec{v}' = \vec{v} - \vec{V}, \quad \vec{B}' = \vec{B}, \quad \vec{E}' = \vec{E} + \vec{V} \times \vec{B} \quad (2)$$

where the primed quantities refer to the new system. It is convenient to eliminate $\vec{E}$ and $\vec{j}$ from Eqs. 1 and to write

$$\frac{\partial \vec{B}}{\partial t} = \nabla \times (\lambda \nabla \times \vec{B}) = \nabla \times (\vec{v} \times \vec{B}) \quad (3)$$

where $\lambda \equiv 1/(\mu\sigma)$ is the magnetic diffusivity. Because of the absence of ferromagnetic effects in the Earth's core, the permeability is usually replaced by the permeability of the vacuum. From the form of Eq. 3 it is obvious that $\nabla \cdot \vec{B} = 0$ remains satisfied if this equation is satisfied by the initial conditions. It is remarkable that Eq. 3 is not only invariant with respect to Galileo transformations and thus compatible with the Navier–Stokes equations of motion, but is also invariant with respect to a transformation to a rotating system.

Since the Earth's outer core can be regarded as an incompressible fluid in first approximation, Eq. 3 can be simplified further by the use of equations $\nabla \cdot \vec{v} = 0$, $\nabla \cdot \vec{B} = 0$,

$$\left(\frac{\partial}{\partial t} + \vec{v} \cdot \nabla \right) \vec{B} - \lambda \nabla^2 \vec{B} = \vec{B} \cdot \nabla \vec{v}, \quad (4)$$

where for simplicity $\lambda = \text{const.}$ has been assumed. This form of the equation of induction is revealing since it resembles the heat equation with the term $\vec{B} \cdot \nabla \vec{v}$ on the right hand side assuming the role of a heat source. This term tends to strengthen the magnetic field when a fluid particle is stretched in the direction of the local magnetic field line. Such an interpretation is especially useful for the dynamo problem.

In order that a magnetic field $\vec{B}$ may grow, the term on the right hand side of Eq. 4 must overcome the effect of the magnetic diffusion term on the left hand side. Using a typical velocity U and a typical length scale d , the ratio of the two terms can be described by the magnetic Reynolds number Rm ,

$$Rm \equiv Ud/\lambda. \quad (5)$$

Only when Rm is of the order of 1 or larger may growing magnetic fields become possible. Necessary conditions of this kind for a dynamo have been derived rigorously by Backus and Childress for a fluid sphere of constant magnetic diffusivity,

$$Rm \equiv Ur_o/\lambda > \pi, \quad (6)$$

where r_o is the radius of the sphere. In Childress's formulation U refers to the maximum velocity, whereas in Backus's formulation $U/\pi r_o$ is the maximum rate of strain of the velocity field.

The simplest dynamo is the disk dynamo originally invented by Faraday and shown in Fig. 2. A metal disk is rotating about its axis with the angular velocity Ω . When the disk is permeated by an initial magnetic field $\vec{B}_0$ parallel to the axis, an electromotive force U_e is generated between axis and rim of the disk,

Geomagnetic Field, Theory, Fig. 2 The disk dynamo

$$U_e = \Omega \int_{r_1}^{r_0} \vec{B}_0 r dr \quad (7)$$

where r_1 and r_0 denote the radii of axis and disk. The electromotive force U_e can be used to drive an electric current J through the circuit indicated in the figure. Denoting by L and R the inductivity and the ohmic resistance of the circuit we obtain for the current J the equation

$$L \frac{dJ}{dt} + RJ = U_e \quad (8)$$

The current J flowing through the circuit is associated with a magnetic field $\vec{B}_1$ which may replace the initial field $\vec{B}_0$. The integral $2\pi \int_{r_1}^{r_0} \vec{B}_1 dr/J$ describes the mutual inductivity M between circuit and disk. Equation 8 for the self-excited disk dynamo can thus be written in the form

$$L \frac{dJ}{dt} = (\Omega M/2\pi - R)J \quad (9)$$

which allows for exponentially growing solutions once the dynamo condition

$$\Omega > 2\pi R/M \quad (10)$$

is satisfied. The exponential growth will be modified, of course, as soon as the Lorentz force $\vec{j} \times \vec{B}$ in the disk has grown sufficiently to affect the angular velocity Ω . A larger torque will then be needed to sustain the rotation speed.

The disk dynamo is an inhomogeneous dynamo since it depends on an inhomogeneous, multiply connected distribution of electrical conductivity as given by the wiring of the circuit. The dynamo would not work if the sense of wiring around the axis would be opposite to that shown in the figure or if it would be immersed in a highly conducting fluid. In this respect, the disk dynamo differs from the homogeneous dynamo operating in the Earth's core in a singly connected finite domain of essentially homogeneous electrical conductivity. Velocity fields required for driving a homogeneous dynamo are necessarily more complex than the simple rotation velocity of the disk dynamo. It can even be proven that a simple form of motion, such as that of the disk dynamo, cannot drive a dynamo in a sphere if λ is a function of only the radial coordinate. More generally, the toroidal theorem states that growing solutions of Eq. 3 do not exist if $\vec{v}$ and λ can be written in the form

$$\vec{v} = \nabla \Psi \times \vec{r}, \quad \lambda = \lambda(|\vec{r}|). \quad (11)$$

In spite of their differences homogeneous dynamos and the disk dynamo share a number of properties:

- (i) For given external parameters there exists always a solution without magnetic field besides the dynamo solution, just as the disk of Fig. 2 can rotate with $\Omega > \Omega_c$ in the absence of any initial field $\vec{B}_0$.
- (ii) The existence of a dynamo solution requires that the magnetic Reynolds number Rm exceeds a critical value Rm_c which corresponds to the quantity $\Omega M/R$ in the case of the disk dynamo. The nonmagnetic solution exists, but it is unstable for $Rm > Rm_c$.
- (iii) Magnetohydrodynamic dynamos always occur in two forms which are identical except for the sign of the magnetic field $\vec{B}$. This property reflects the fact that the Lorentz force is given by an expression that is quadratic in $\vec{B}$.

Property (iii) is the basic reason that the geomagnetic field has often switched its polarity in the geologic past. These “reversals” have occurred nearly randomly about every 200,000 years in the time average. In contrast, the solar magnetic field reverses every 11 years in a surprisingly periodic fashion.

For the description of magnetic fields associated with a spherical system one often uses the general representation for a solenoidal vector field,

$$\vec{B} = \nabla \times (\nabla h \times \vec{r}) + \nabla g \times \vec{r} \quad (12)$$

in terms of a poloidal and a toroidal component each of which is described by a scalar function, the poloidal function h , and the toroidal function g . Without loss of generality, the averages of h and g over surfaces $|r| = \text{const.}$ can be assumed to vanish. A homogeneous dynamo usually requires the interaction of both components. The functions h and g can be separated into their axisymmetric parts $\bar{h}$ and $\bar{g}$ and non-axisymmetric parts, $h = h - \bar{h}$ and $g = g - \bar{g}$. Because of Cowling’s theorem the latter parts play an essential role in the dynamo process. The component $\bar{g}$ can easily be generated in a spherical dynamo through a stretching of the axisymmetric poloidal field by a differential rotation. This process is known as the ω -effect. But the amplification of $\bar{h}$ requires the interaction of the nonaxisymmetric components of magnetic fields and velocity fields. This is often called the α -effect. This latter effect can also be used, of course, for the generation of $\bar{g}$ in the absence of a differential rotation. One thus distinguishes $\alpha\omega$ - and α^2 -dynamos. These concepts were originally introduced within the framework of mean-field magnetohydrodynamics for which we refer to the book of Krause and Raedler (1980).

Energetics of the Geodynamo

For a prescribed stationary velocity field, Eq. 3 admits solutions with an exponential time dependence, of which the

growing ones are called dynamos. As the magnetic field grows, the action of the Lorentz force on the velocity field can no longer be neglected. The work done by the velocity field against the Lorentz force equals the energy consumed by ohmic heating. Thus, the sustenance of a finite-amplitude magnetic field against ohmic dissipation requires a source of mechanical energy. A lower bound of about $10^8 W$ on the ohmic heating in the Earth’s core can be obtained by a calculation of the minimum dissipation corresponding to the observed geomagnetic field, while an upper bound of about $10^{13} W$ is given by the observed geothermal heat flux. A realistic value is likely to be within the range 10^{11} to $10^{12} W$.

Numerous sources of energy for the geodynamo have been considered in the history of dynamo theory. The major ones that cannot be excluded right away are the precession of the Earth, thermal heat sources, and compositional buoyancy. The latter source first proposed by Braginsky in 1963 is probably the largest contributor, since the turbulence induced by precession appears to be marginal and since the Carnot efficiency of heat sources is relatively low (Gubbins et al. 2004). Compositional buoyancy is generated by the growing solid inner core. Iron and perhaps nickel crystallize at the inner core-outer core boundary while lighter elements stay in solution. The decrease in density caused by the increase in the concentration of light elements provides a source of potential energy that can drive convection in the outer core. Since the outer core contains about 10% light elements by weight, most likely silicon, sulfur and oxygen, the buoyancy provided by this process appears to be more than adequate to drive the geodynamo. The compositional buoyancy mechanism has the advantage that it could explain the apparent absence of a dynamo in the case of Venus (Stevenson et al. 1983; Nimmo 2002). Since Venus resembles the Earth in most respects, the absence of a measurable magnetic field has posed a puzzle. The somewhat higher pressure at the Earth’s center and the more efficient heat transport out of the planet because of plate tectonics seem to have allowed the inner core to form, whereas Venus will reach this stage of its thermal history much later. Estimates for the age of formation of the inner core of the Earth range from 1 to 2 b.y. Since evidence for geomagnetism exist for earlier times in the paleomagnetic record when the inner core had probably not yet nucleated, thermal buoyancy generated by cooling and possibly by radioactive elements is likely to have played a role in driving the geodynamo in the Earth’s early history. In this respect the Earth resembles the major planets for which thermal buoyancy appears to be the only viable source of energy to drive the planetary dynamo.

The way in which compositional buoyancy drives convective motion in the outer core is not well understood. It is even possible that the outer part of the outer core is stably stratified. Another peculiar property of the solidification process at the inner core is the so-called mushy zone in which liquid and

Geomagnetic Field, Theory, Table 1 Properties of the liquid outer core of the Earth

Property	Symbol	Value	Unit
Angular velocity of rotation	Ω	$7.27 \cdot 10^{-5}$	s^{-1}
Mean outer radius	r_o	3485 ± 3	km
Mean inner radius	r_i	1225 ± 15	km
Density	ρ	$9.9 - 12.2$	$10^3 kg/m^3$
Coefficient of thermal expansion	α	10^{-5}	K^{-1}
Thermal diffusivity	κ	$5 \cdot 10^{-6}$	m^2/s
Magnetic diffusivity	λ	2	m^2/s
Kinematic viscosity	ν	10^{-6}	m^2/s
Permeability of vacuum	μ_0	$4\pi \cdot 10^{-7}$	H/m

solid phases coexist (see ► “Earth’s Structure, Core”). But those details have little influence on the theory of the geodynamo in its current state. Since the form of motion in the outer core is primarily determined by Coriolis and Lorentz forces the theory of geomagnetism has proceeded without distinguishing much between thermal and compositional buoyancy.

Some typical values of parameters used in the theory of the geodynamo are given in Table 1.

Magnetohydrodynamic Theory of the Geodynamo

The theory of the geodynamo requires the inclusion of the equations of motion for the rotating liquid core for several reasons. First of all, constraints on the velocity fields used in the dynamo equation are needed since rather arbitrary velocity fields are capable of generating fields that resemble the observed geomagnetic field. The velocity fields driven by geophysically realistic forces share special properties, such as the approximate alignment of the vorticity with the axis of rotation, that make them useful in the interpretation of certain features of the observed magnetic field. The second reason for including the equations of motion stems from the necessity of taking into account the Lorentz force without which an equilibrium amplitude of the magnetic field cannot be determined. Thirdly, the time dependence of the geomagnetic field cannot be understood without a detailed knowledge of the dynamics of the velocity field in the core. The basic equations of motion for the velocity vector $\vec{v}$, the heat equation for the deviation Θ from the static temperature distribution, and the equation of induction for the magnetic flux density $\vec{B}$ are usually written in the following form:

$$\nabla \cdot \vec{v} = 0, \quad \nabla \cdot \vec{B} = 0, \quad (13)$$

$$\begin{aligned} & \left(\partial_t + \vec{v} \cdot \nabla \right) \vec{v} + 2\Omega \vec{k} \times \vec{v} \\ & = -\nabla \pi + \alpha \Theta g \vec{r} + \nu \nabla^2 \vec{v} + \vec{B} \cdot \nabla \vec{B} / \rho \mu, \end{aligned} \quad (14)$$

$$\partial_t \Theta + \vec{v} \cdot \nabla \Theta = \vec{v} \cdot \nabla T_s + \kappa \nabla^2 \Theta, \quad (15)$$

$$\lambda \nabla^2 \vec{B} = \partial_t \vec{B} + \vec{v} \cdot \nabla \vec{B} - \vec{B} \cdot \nabla \vec{v}, \quad (16)$$

where ∂_t denotes the partial derivative with respect to time t and where $-g \vec{r}$ denotes the force of gravity. ν is the kinematic viscosity, $\vec{k}$ is the unit vector of the axis of rotation and Ω is the angular velocity of rotation. The potential temperature distribution T_s describes the difference between the temperature distribution for the static solution of the problem and the adiabatic temperature distribution with the same temperature at the inner core boundary. As mentioned before, Eq. 15 remains essentially unchanged if T_s and Θ are interpreted a concentration of light elements. In that case the coefficient of thermal expansion α and the thermal diffusivity κ just need to be reinterpreted. All gradient terms in the equation of motion have been combined into $\nabla \pi$. In writing Eqs. 13, 14, 15, and 16, we have assumed the Boussinesq approximation implying constant material properties and a constant density ρ except in the gravity term.

Using a dimensionless description, the parameters of the problem can be reduced to four dimensionless groups, the Rayleigh number Ra , the Coriolis number τ , the Prandtl number Pr , and the magnetic Prandtl number Pm which are defined by

$$\begin{aligned} Ra &= \frac{\alpha g \Delta T d^4}{\nu \kappa}, & \tau &= \frac{2\Omega d^2}{\nu}, \\ Pr &= \frac{\nu}{\kappa}, & Pm &= \frac{\nu}{\lambda}, \end{aligned} \quad (17)$$

where the thickness d of the spherical shell has been used as length scale and ΔT is the difference of the potential temperature between the inner core-outer core boundary and the core-mantle boundary. Instead of the Coriolis number often its inverse, the Ekman number $E = \tau^{-1}$ is used. Since λ/ν is roughly 10^6 in the Earth’s core the main sink of mechanical energy is ohmic dissipation and it is generally believed that the term $\nu \nabla^2 \vec{v}$ is unimportant except close to the rigid boundaries of the liquid core. Moreover, the magnetostrophic approximation is often applied in which the inertial term $\left(\partial_t + \vec{v} \cdot \nabla \right) \vec{v}$ is neglected in comparison to the Coriolis force. Without these terms the important Taylor constraint can be derived: After integrating the azimuthal component of Eq. 14 over a coaxial cylindrical surface in the liquid core, one must conclude that an accelerating differential rotation occurs unless the condition

$$\int \int \left[(\nabla \times \vec{B}) \times \vec{B} \right]_\varphi s d\varphi dz = 0 \quad (18)$$

is satisfied for every distance s from the axis. In deriving Eq. 18, we used the fact that the inflow across the cylindrical surface is balanced by the outflow with the result that the contribution from the Coriolis force term vanishes. Different strategies have been designed to accommodate the Taylor constraint (Eq. 18). In Braginsky's (1978) model Z the friction of the viscous Ekman layer at the solid surface of the sphere provides a balance on the right side of Eq. 18. But this effect is small such that the constraint of Eq. 18 becomes nearly satisfied by a poloidal field that is extended parallel to the axis of rotation except for the region close to the boundary.

In modern numerical simulations of convection driven dynamos in rotating spherical shells the Taylor constraint (Eq. 18) is usually not approached because relatively high values of the kinematic viscosity must be assumed for numerical reasons and also because the inertial term $(\partial_t + \vec{v} \cdot \nabla) \vec{v}$ plays a larger role than it possibly plays in the geodynamo. Instead of an Earth-like ratio, values of the order unity for λ/ν are used to ensure numerical convergence. The high value of ν is interpreted as an eddy viscosity which is supposed to represent the dissipative action of small scale components of the velocity field which cannot be resolved in the numerical simulations.

It is instructive to consider Eqs. 13, 14, 15, and 16 in the limit of a vanishing magnetic field. In that case the dominant terms are the Coriolis force and the pressure gradient, the balance of which,

$$2\Omega \vec{k} \times \vec{v} = -\nabla \pi \quad (19)$$

is called the geostrophic balance. The curl of Eq. 14 together with $\nabla \cdot \vec{v} = 0$ gives rise to the Proudman–Taylor theorem

$$\Omega \vec{k} \cdot \nabla \vec{v} = 0 \quad (20)$$

which states that steady motion of a rotating inviscid fluid must not depend on the coordinate in the direction of the axis of rotation. Convection in a sphere requires, however, a finite radial velocity component and therefore cannot fully satisfy condition (20). As a result nonmagnetic solutions of Eqs. 13, 14, 15, and 16 exhibit a time dependence in the form of a drift in the prograde azimuthal direction. In addition they are characterized by small length scales in the directions perpendicular to the axis of rotation whereby viscous friction is increased. A sketch of the motion at the onset of convection in a homogeneously heated sphere is shown in Fig. 3. For details on the dynamics of these convection columns and their dynamo action, we refer to the review article by Busse (2002).

Geomagnetic Field, Theory, Fig. 3 Sketch of convection columns in a rotating, internally heated sphere for Rayleigh numbers close to the critical value

Because of the small viscosity in the Earth's core, the Lorentz force offers a more effective release of the rotational constraint expressed by condition (20) than does viscous friction. The simplest approach to this problem is to consider the onset of convection in the presence of an azimuthal magnetic field of strength B_0 (Fearn 1979). The analysis shows that the scale of the preferred mode of convection increases dramatically as B_0 is increased and the critical value of the Rayleigh number and the drift rate decrease. The dimensionless parameter governing this effect is the Elsasser number

$$\Lambda = \frac{B_0^2}{2\Omega\mu_0\rho\lambda} \quad (21)$$

which describes the ratio between Lorentz and Coriolis forces. When the magnetic field becomes very strong such that Λ exceeds unity, it exerts an inhibiting influence on convection. It turns out that the minimum Rayleigh number for the onset of convection is achieved for $\Lambda \approx 1$. Eltayeb and Roberts suggested in 1970 that this condition is likely to determine the equilibrium strength of the magnetic field inside the Earth's core. While the condition $\Lambda \approx 1$ appears to fit the amplitude of the geomagnetic field reasonably well,

numerical simulations of spherical dynamos do not provide much support for such a relationship. In fact, the dynamical effect of a magnetic field generated by dynamo action is quite different from that of an imposed magnetic field. In present geodynamo models, it does not seem to affect the scale of convection significantly nor has it been found that it allows convection to exist at Rayleigh numbers below the critical value for onset of convection in the absence of a magnetic field.

There is still no general agreement about the relationship that governs the average strength of the magnetic field reached in the dynamo process. But it appears likely that the available energy for driving motions determines the average strength of the magnetic field as has been proposed by Christensen and Aubert (2006).

The velocity field displayed in Fig. 3 is symmetric with respect to the equatorial plane. Even in its turbulent state the convection flow retains approximately this symmetry outside the tangent cylinder which touches the inner core at its equator. Because of this symmetry, the solutions $\vec{B}$ of Eqs. 13, 14, 15, and 16 can be separated into two classes: a quadrupolar class that has the same symmetry with respect to the equatorial plane as the velocity field, and a dipolar class that exhibits the opposite symmetry. In both cases the Lorentz force is compatible with the symmetry of the velocity field. The observed geomagnetic field is primarily a dipolar field and so are most of the other planetary magnetic fields, but from a basic point of view quadrupolar dynamos are not less likely. The more complex structure of their poloidal field is balanced by the simpler form of their zonal component. The latter is symmetric with respect to the equatorial plane, whereas it is antisymmetric in the dipolar case. The observed geomagnetic field includes a substantial contribution from quadrupolar terms which is not surprising, since the symmetry property exhibited in Fig. 3 does not hold inside the tangent cylinder. Moreover, the thermal conditions at the core surface are not likely to be spherically homogeneous because of convection in the Earth's mantle.

The solution of Eqs. 13, 14, 15, and 16 becomes much simpler when the geometry of the spherical shell is replaced by that of a cylindrical annulus with a height decreasing with distance from the axis. An early analytical model (Busse 1975) demonstrates that the dynamo action of convection columns such as those shown in Fig. 3 depends on their helicity. The latter is defined as the azimuthal average over the vorticity multiplied by the velocity vector, $\vec{v} \cdot (\nabla \times \vec{v})$. The helicity is generated for example in the columns through the suction exerted by the Ekman layers at the upper and lower boundaries and by the finite change in height of the columns with distance from the axis. This helicity effect appears to dominate also in modern numerical simulations of the geodynamo.

Time Dependence of the Geodynamo

From observations of the secular variation and from the paleomagnetic evidence for reversals of the direction of the geomagnetic field, it is clear that the mechanism of the geodynamo is not steady. Since a complete model of the geodynamo does not yet exist, the various features that may lead to the observed time dependence cannot be derived from basic mechanisms. Thus, the theories of secular variation and of reversals rely on simplifying assumptions (see ► “[Geomagnetic Field, Secular Variation](#)” and ► “[Geomagnetic Field, Polarity Reversals](#)”). As simulations of the geodynamo become more refined, however, the observed secular variation and the increasing body of data on the process of excursions and reversals will be important for discriminating between different models of the geodynamo.

The time dependence of the nonaxisymmetric part of the magnetic field is a result of the basic dynamics discussed in the preceding section. Even without a magnetic field, the convection motion exhibits a time dependence in the form of a prograde or eastward drift at slightly supercritical Rayleigh numbers, to which a chaotic variability is added as convection becomes more vigorous. In the presence of a magnetic field, this drift is decreased substantially because the Lorentz force balances the ageostrophic part of the Coriolis force. The order of magnitude of the drift corresponds roughly to the observed westward drift of the nondipole part of the geomagnetic field. But since there is likely to be a zonal flow of the liquid core relative to the mantle of a similar order of magnitude, no direct comparison between theoretical and observed drift rates can be made without further knowledge about the velocity field in the core.

The geomagnetic time dependence of internal origin with the shortest duration is known as “geomagnetic jerk.” This term refers to rather abrupt changes in the second derivative with respect to time of the East-West component of the geomagnetic field over the time span of a year or so. Geomagnetic jerks are likely to be the result of magnetohydrodynamic waves in the outer core (Blokhin et al. 2002).

In contrast to the solar magnetic field, the geomagnetic field does not reverse in nearly periodic intervals. The time-scale of reversals is an order of magnitude larger than the timescale of about 2×10^4 years for the diffusive decay of Earth's magnetic field. This may suggest the geodynamo is basically a steady dynamo. Recent evidence (Roberts 2008) suggests, however, that geomagnetic excursions, in which the dipole moment of the Earth decreases to almost vanishing values for a time span of the order of a 1000 years, occur much more frequently than reversals. No consensus about the origin of excursions and reversals has yet been achieved.

Outlook

In the past two decades, the dynamo theory of geomagnetism has progressed enormously through increasing availability of computer resources; see ► [“Core Dynamo”](#). This development will continue in the future with the main goal of reaching higher (and thus more realistic) values of the Coriolis number. Ultimately the lack of data on properties of the Earth’s core and lower mantle will inhibit the progress in understanding the geodynamo.

For a more detailed exposition of the foundations dynamo theory and the associated fluid dynamical concepts, the reader is referred to the book edited by Dormy and Soward (2007) and the book by G. Glatzmayer (2014). A recent review of computational results related to the geodynamo can be found in the article by J. Wicht and S. Sanchez (2019).

Definition

Geomagnetically induced current (GIC)

Intense, low-frequency, quasi-direct currents flowing in the conductor systems owing to rapid changes of the geomagnetic fields

Space weather

Dynamic variations at the Sun and in interplanetary space disturbing the near-Earth space environment creating conditions that are hostile to space-borne and ground-based technological systems and can even impose danger to human life

Introduction

Geomagnetically induced currents (GICs) are intense, low-frequency (~ 0.001 – 1 Hz) currents flowing in Earth-ground conductor systems owing to rapid changes of the geomagnetic fields ($dB/dt > 1$ nT s^{−1}) (Campbell 1980; Akasofu and Aspinnes 1982). According to Faraday’s law of induction, a

fluctuating geomagnetic field induces geoelectric fields which drive GICs in the ground and electrical power systems. The induced currents are essentially quasi-DC as their frequencies are much less than the frequency of the electrical grids operating at 50 or 60 Hz.

Intense GICs are known to cause extensive and expensive damages to a variety of technological systems such as electric power systems, telecommunication cables, and natural gas pipelines. Strong GICs enter the neutral grounding of transformers (operating typically at ~ 50 Hz frequency) causing transformer core magnetic flux increase and consequent half-cycle saturation of the core. These in turn distort the AC waveform of the power signal, which can lead to transformer overheating, system-relay interference, reactive power loss, or even system damage.

Space Weather Events and Geomagnetically Induced Currents

Space weather generally refers to the physical conditions in the Sun-Earth system that can affect the performance of spacecraft and ground-based technological systems, including electric power distribution systems. The solar sources of the space weather are the solar activity transients such as solar flares and coronal mass ejections (CMEs), solar wind high-speed ($\sim 550\text{--}800$ km s $^{-1}$) streams (HSSs), and corotating interaction regions (CIRs) formed by the HSS interaction with slow ($\sim 300\text{--}400$ km s $^{-1}$) solar-wind streams. During all of the above phenomena, significant variability occurs in the solar-wind speed, plasma density, and strength and direction of the magnetic field. The dynamics of geospace, extending from the Earth's plasma environment called the ionosphere to the protecting magnetic bubble called the magnetosphere, is largely affected by this solar-wind variability.

Magnetic reconnection between the interplanetary magnetic field (IMF) and the dayside geomagnetic field is considered to be the main mechanism of energy transfer from solar wind to the Earth's magnetosphere (Dungey 1961). The process of magnetic reconnection works most efficiently when IMF is directed southward, opposite to the dayside magnetopause magnetic field direction (Tsurutani and Gonzalez 1997). Dayside magnetic reconnection leads to injection and storage of solar wind kinetic energy (energetic particles) in the magnetotail. This causes stretching of the magnetotail and formation of a near-Earth neutral line. Onset of magnetic reconnection at this neutral line gives rise to an explosive release of energy from the magnetotail toward the inner magnetosphere. This near-midnight plasma injection excites a substorm (Tsurutani and Meng 1972), and auroras in the high-latitude nightside ionospheric region. If the southward IMF is intense with hours duration, such as during the magnetic cloud portion of an interplanetary coronal mass ejection

(ICME) (Burlaga et al. 1981), the plasma injection is deeper and the particles get energized to $\sim 10\text{--}300$ keV. This leads to intensification of the ring current which produces a diamagnetic decrease in the Earth's magnetic field measured at near-equatorial magnetic stations. This latter effect is the *main phase* of the geomagnetic storm. After the storm main phase is over, the decay of the ring current starts the *recovery phase* of the magnetic storm. The energetic particles are lost by several physical processes, namely, charge-exchange, Coulomb collisions, wave-particle interactions, and convection out the front side of the magnetopause (Kozyra and Liemohn 2003).

The intensity of the magnetic storm is measured by the disturbance storm time (Dst) index, an hourly geomagnetic activity index, or by the SYM-H index with a temporal resolution of 1 min. The intensity of a substorm is measured by the auroral electrojet (AE) index. The intensities of both substorms and magnetic storms are expressed in nT. During intense magnetic storms, near-equatorial magnetic field disturbances of a few 100s nT are recorded for a few hours to days. This ground magnetic effect is due to the magnetospheric ring current which exists from $L = 2$ to $L = 8$ (L is the distance in Earth's radius R_E that a dipole magnetic field crosses the magnetic equator). During super magnetic storms, the magnetic disturbances could be higher, exceeding 1000 nT at times. Substorms cause high-latitude ground-magnetic disturbances from ~ 100 to 1000s nT lasting for a few minutes to hours. These magnetic effects are due to a combination of the auroral electrojet which is located in the ionosphere at a height of ~ 100 km and field-aligned currents coming from the magnetosphere to the ionosphere. The ring current effects of substorms are relatively minor compared to that of magnetic storms. During magnetic storm main phases, many substorms may also occur.

A second means of energy transfer from the solar wind to the magnetosphere is sudden solar wind ram pressure changes. One mechanism is the pressure pulse due to high plasma densities sunward of fast magnetosonic shocks (Kennel et al. 1985). These cause sudden impulses (SI $^+$ s), strong changes of the equatorial magnetic field of 10–100 nT with $\sim 1\text{--}10$ min durations (Araki 1977), the triggering of nightside substorms (Heppner 1955), and in extreme cases, the formation of new radiation belts (Blake et al. 1992).

Geomagnetic field disturbances associated with magnetic storms and substorms are known as the key factor for the generation of GICs. Strongest GIC events are recorded in the high ($>50^\circ$) geomagnetic latitude zone in association with large amplitude magnetic field fluctuations during intense and frequent auroral activities (Pirjola 2000). However, recent studies show evidence of mid-to-low latitude GICs in association with SI $^+$ events caused by solar wind ram pressure impingement on the dayside magnetopause of the Earth (Gaunt 2014; Carter et al. 2015).

Generation of GIC Events

A GIC event is generated by the high-frequency changes in geomagnetic fields due to space weather events. Geomagnetic storms, substorms, supersubstorms, magnetic pulsations, and sudden impulses (SI^+) are the major drivers for the generation of GICs (Pulkkinen et al. 2005; Viljanen et al. 2006; Ngwira et al. 2014; Tsurutani et al. 2020). In fact, a GIC event is essentially the ground manifestation of the complex space-weather chain starting from the solar eruptions, extending to the interplanetary space, and then to the surface of the Earth and below. Therefore, the GIC signals carry information about the processes involved in the Sun-Earth connection and space weather. Most models calculate GIC either from the measurements of geomagnetic field (B) and its time derivative dB/dt using magnetometers or from the magnetotelluric measurements of both B field and electric field E (Gaunt 2016; Pulkkinen et al. 2017).

Systematic studies on GICs and their effects on the electric power systems were started first in the high-latitude countries, e.g., Finland (Viljanen and Pirjola 1994) and Canada (Boteler 2001), where GICs might be expected to occur. Later, the GIC studies have been undertaken in the low- and mid-latitude regions such as Scotland, China, Japan, South Africa, Brazil, New Zealand, and Australia. An excellent overview of GIC impacts on electrical power systems is given by Gaunt (2016). Direct current (DC) blocking devices, such as neutral-point reactors and series capacitors, are being designed and installed in high voltage transmission grids to mitigate the flow of GICs through transformers (Kappenman et al. 1991; Thomson et al. 2010). The real-time monitoring of GICs provides a useful means to understand the power-system status, but it does not guarantee that the system will survive a future severe GIC event (Erinmez et al. 2002). At present, no reliable forecastable model for GICs exists (Gaunt 2016).

The severity of the GICs flowing through ground-based technological systems depends on several factors such as severity of the magnetic disturbances in the magnetosphere-ionosphere system, location and configuration of the system (i.e., power transformers, transmission lines, etc.), and conductivity of the Earth's surface and interior, coastal effects, etc. (Clilverd et al. 2018; Liu et al. 2018). The highest GIC levels occur for the fastest rate of change of the magnetic field. Therefore, dB/dt is considered as an important parameter to quantify the relative level of GIC threat. For example, the Québec power station blackout during the 13–14 March 1989 magnetic superstorm occurred when the peak dB/dt was ~ 480 nT/min. Recent study of the March 1989 magnetic storm by Boteler (2019) shows that the peak dB/dt occurred during a shock-induced substorm, much before this superstorm attained its peak $Dst = -589$ nT value. It is interesting to note that dB/dt values exceeding 2000 nT/min have been observed, and much higher values ~ 5000 nT/min might have

occurred during historic magnetic storms (Kappenman 2006). Recent studies show that compression of the magnetosphere caused by interplanetary shock impacts, discussed earlier, increases the magnetopause currents leading to large dB/dt variations in the mid- to low- latitudes as well as in the equatorial electrojets (Carter et al. 2015; Oliveira et al. 2018). Furthermore, in many magnetic storms, the GICs due to the SI^+ can be much larger than those recorded at the same station during the storm main phase (Zhang et al. 2015). Thus, even the power stations situated near the equatorial electrojet are susceptible to GIC risks. For maximum possible dB/dt values due to SI^+ s, we refer the reader to Tsurutani and Lakhina (2014).

Future Outlook

Impacts of GICs on electric power systems, natural gas pipelines, and telecommunications have direct socioeconomic impacts. This can be understood from some historical examples of large GIC events. The largest recorded magnetic storm at Earth with a peak $Dst = -1760$ nT was caused by a CME associated with an extremely intense solar flare on 1 September 1859 (Tsurutani et al. 2003). GICs on telegraph lines caused arcing that led to fires and electrical shocks (Loomis 1861). Two recent examples of GIC-related hazards are the collapse of the entire Hydro Québec power system during a superstorm (with peak $Dst = -589$ nT) on 13–14 March 1989 (Allen et al. 1989), and the transformer collapse near Malmö in Sweden during the 29–30 October 2003 superstorm (with peak $Dst \sim -400$ nT) (Pulkkinen et al. 2005; Wik et al. 2008). Due to growing dependence of modern society on electric technology (and greater vulnerability), large GIC impacts are now realized to be quite damaging to society as they can disrupt functioning of the power grids and communication cables, and cause erosion of oil and gas pipelines (Royal Academy of Engineering report 2013; Pulkkinen et al. 2017). Currently GICs are considered as the greatest space-weather hazard globally.

There has been tremendous progress in understanding the space weather processes and generation of GICs during the past two decades. An exhaustive review on the current status and future challenges of space-weather physics and solar-terrestrial physics (STP) is given by Tsurutani et al. (2020). The ultimate challenge for the space community is to predict the occurrence of extreme magnetic storms and their associated extreme GICs. Although extreme events are rare, yet they are the ones that can cause the maximum damage. Presently, there is a limited understanding of the upper limit for the geoelectric fields that drive GICs. Additionally, the prediction of GICs with a lead time of 1–3 days is very limited or unreliable (Gaunt 2016; Pulkkinen et al. 2017) as reliable estimates for the strength of magnetic storms a couple of

days in advance are not available. The major sources of uncertainty are prediction of the IMF southward components associated with the ICME and in the sheath region behind the interplanetary shock. Solar wind measurements taken upstream of the Earth at the Lagrange 1 (L1) point by NASA's Advanced Composition Explorer (ACE) and Deep Space Climate ObserVatoRy (DSCOVR) are being used to provide reliable estimates on the solar-wind drivers. This information is used in the physics-based and empirical models to calculate the currents in the magnetosphere and ionosphere to make real-time prediction of GICs with a lead time of ~30 min or so. For extreme events, such short-time notice is not sufficient to put any mitigation plan in place against hazardous extreme GICs. Since GICs depend on the ground conductivity and characteristics of regional power grids, it is a big challenge for the modelers to develop global GIC models that can predict the magnitude and duration of GIC events in different parts of the world.

Borehole geophysics

Definition

Borehole geophysics includes all methods that make continuous profiles or point measurements at discrete depth stations in a borehole. These measurements are made by lowering different types of probes into a borehole and by electrically transmitting data in the form of either analog or digital signals to the surface, where they are recorded as a function of depth. The measurements are related to the physical and chemical properties of the rocks surrounding the borehole, the properties of the fluid saturating the pore spaces in the formation, the properties of fluid in the borehole, the construction of the well, or some combination of these factors.

Introduction

The science of well logging was begun by Conrad Schlumberger in 1927 as an application of his work on resistivity measurements of the earth in surface exploration (see ► [“Electrical Resistivity Surveys and Data Interpretation”](#)). From the early measurement of electrical properties by means of normal and lateral resistivity curves, modern logging has progressed through such changes as the introduction of wall-contacting microspacing device, dipmeters, and conductive and inductive techniques. Parameters other than electrical have been utilized, such as radioactive properties of rocks both passive and forced as a result of bombardment by both gamma rays and neutrons; the measurement of acoustic properties, the measurements of other rock properties and auxiliary technique developments such as dielectric logging, temperature log, downhole viewers, remote sensors (dipmeter log, radar system, borehole gravimeter), etc.

The rapid advancement of well-logging techniques is observed in the 1980s and 1990s with the motivation of the petroleum industry to develop ever more cost-effective technology to evaluate thin-bed and nonconventional reservoirs. At the same time, geophysical technology also advanced rapidly with development of new techniques and improved mathematical methodology. The increased use of array tool design (multiple sources and receivers) provides improved vertical resolution, improved and multiple depths of investigations, and enables radial and azimuthal imaging by resistivity tools. Cased-hole resistivity logging may be realized, what could not be possible earlier. Acoustic-array designs, using either dipole or quadrupole sources, can acquire high-quality shear wave data in most types of reservoir rocks. A new generation of nuclear magnetic resonance (NMR) tools using pulseecho technology provides an improved measurement without the operational restrictions of earlier tools. Nuclear tools have been improved by the use of new high-density gamma-ray detectors that allow higher logging speeds and better repeatability and permit a slimhole, through-tubing

tool design. Renewed interest in neutron activation methods has produced new tools based on oxygen and silicon activation, like the pulsed-neutron source sensor. Improvements to existing resistivity and nuclear measurement-while-drilling (MWD) tools plus new caliper and acoustic porosity devices and measurement at the bit, ensure that MWD will continue to replace wireline logging in many situations. High angle, horizontal, and slimhole wells are now common as a result of advances in drilling technology. Wireline and MWD logging have been adapted for use in these wells; and new directionally focused resistivity tools have been developed; logging on coiled tubing is now routine. Improvements of downhole microprocessor-based technology and high-speed digital telemetry make possible the use of high data-rate array and imaging tools as well as increased possibilities of combinations of different tool types. Concurrent improvements in uphole computer processing combined with new visualization techniques made possible by the advent of powerful desktop computers enhance presentation and interpretation of the data acquired with these tools.

A chronological listing of these developmental steps is presented in literature (Johnson 1962; Segesman 1980; Prensky 1994). The applications for geophysical welllogging methods continue to expand away from exploration for natural resources (oil and gas, water, minerals, geothermics) into the field of civil engineering, rock mechanics, disaster prevention, and environmental preservation. Information about recent and emerging developments and trends in well-logging and rock-characterization technology offer a lot of publications from meetings of geophysical societies (proceedings) and geophysical journals and books.

The main objective of borehole geophysics is to obtain more information than can be obtained from conventional drilling, sampling, and testing. Drilling a borehole or well is expensive, but the borehole provides access to the subsurface for geophysical probes. The most obvious log is a description of extracted cores, to provide information of lithology, microfossils, permeability, porosity, and fluids. These logs are used for geological correlation between different wells across an oil field and for the quantitative interpretation of the geophysical logs. The ideal would be to obtain continuous core, but this is very slow and thus expensive, therefore, it is done only for formations of special interest, usually potential oil-producing formations when they can be identified in advance. After drilling, samples may be obtained by sidewall sampling. Samples of fluids from surrounding rocks are also taken with a formation tester. Borehole logs provide continuous records that can be analyzed in real time at the well site. Thus, they can be used to guide completion or testing procedures. Log data are readily reproduced over long periods. Logs also aid the lateral and vertical extrapolation of geologic and fluid sampling data or hydraulic test data obtained from wells. In contrast, samples of rock or fluid from a borehole provide data

only from sampled depth intervals and only after laboratory analysis. Data from some geophysical logs, such as acoustic velocity and resistivity, are also useful in interpreting surface geophysical surveys.

The manner in which a well is drilled affects the logging environment, through such factors as the resistivity of the fluid in the well bore, the diameter of the well, the roughness (rugosity) of the borehole wall, and the mudfiltrate invasion of porous formations surrounding the well. The thickness and composition of material between a logging probe and the borehole wall can have an effect on the data set. In general, the larger the borehole diameter, the poorer the quality of the geophysical logs obtained.

Wellbore Environment

The physical properties of the geological formations in the vicinity of a borehole are often affected by the drilling process. Further, the temperature, lithostatic stress, and fluid pressure increase with depth. Logging cable and tools must be constructed in such a way that can withstand the highest temperatures and pressures encountered in the well. Interpretation of well-log data may commonly require temperature correction.

Drilling is usually done using a rotating bit that grinds away the formations to produce cuttings from shales, sand from unconsolidated sandstones, or chips up to a few millimeters in size from solid rocks. The bit is fitted to the bottom of the drill stem, which typically consists of 10-m lengths of steel pipe screwed together. The bit may be turned by rotating the whole drill string of 10 m pipes from its top, but more commonly nowadays the bit is turned up by the mud being pumped through the turbine just behind the bit. Turbine drilling allows much greater control of drilling direction.

Down through the drill stem is pumped drilling fluid, commonly termed mud. It is a mixture of ingredients (liquid and solids) formulated to produce the required rheological properties such as density and viscosity. Drilling mud expedites the drilling operation by cooling, lubricating and cleaning the bit, reducing friction, and transporting cuttings from bit to the surface. Mud also serves to stabilize the wall of the hole, and – by its weight – to prevent any high-pressure gas encountered from blasting out of the hole, and also forms a mud cake, which is a layer made up of the solids in the mud deposited on the sides of hole opposite an intergranular permeable formation ensuring that the hydrostatic pressure of the drilling mud is higher than that of groundwater. The formation is invaded by the liquid of the mud, the mud filtrate, to a distance that depends on the porosity of the formation and properties of the mud. Nearest to the hole is the flush zone, in which the fluids are entirely mud filtrate (apart from some residual fluid that cannot be removed); next is the transition

zone, with decreasing replacement until a sufficient distance is the uninvaded zone, quite unaffected by the drilling. In very permeable and porous formations, the mudcake builds up quickly and forms a barrier to further invasion. In less-permeable, low-porosity formations, the buildup is slow and invasion can be very deep. Thus, the resistivity of permeable rocks changes markedly because of the origin of these radial zones (Schlumberger 1987). In pelitic formations (claystones, siltstones), the changes in elastic and mechanical (strength) properties occur along the borehole walls. Under the influence of drilling mud, the clay minerals swell and the cohesion of the rock is reduced; a low-velocity zone is formed along the borehole wall in the pelitic formations, being the more marked the longer the time interval between drilling and the moment of velocity measurement.

Calibration and Standardization of Logs

Standardization of logging measurements is the process of checking the response of logging probes in the field, using some type of portable field standard, usually before and after logging a well, to provide the basis for system drift correction in output with time. The Gamma-ray calibration pit and Neutron pit of the American Petroleum Institute (API) in the University of Houston are generally accepted over the world as a basic standard for nuclear logs because of definition of the API Gamma-ray unit and API Neutron unit.

Calibration is the process of converting measuring units of log response to units that represent rock characteristics. Calibration facilities should closely simulate the lithology and geometry to be logged. In many applications, it becomes difficult to utilize such calibration facility for several reasons (namely, the local lithologic environment substantially differs from lithology of calibrations blocks). Then, the calibration is performed by developing a regression between the measured geophysical property (the log) and the property of interest determined from laboratory tests using recovered core. The necessary condition is that the boreholes under study have been carefully cored. In principle, the quality of calibration is indicated by the correlation coefficient given from the regression. This calibration approach is also called “method of key beds.”

Benefits and Limitations of Logging

Well logging differs from most other geophysical methods, not only in being carried out down a borehole, but in relating the physical quantities measured more specifically to geological properties of interest, such as lithology, porosity, and fluid composition. Their main advantage is greater detail, the measurements are made within formations of interest and can be

compared with the geological information obtained from the same hole. Borehole logs usually provide continuous data that can be used to guide testing procedure and thus may reduce the number of samples needed and in this way the cost. The data are useful for interpreting surface geophysical surveys. Log data are repeatable over a long period. The repeatability and comparability provide the basis for measuring changes in exploitation wells. Changes in quality of casing, such as grade of corrosion, clogging, or changes in exploitation regime, may also be recorded.

Well logging cannot replace sampling completely. Background information is needed on each new geologic environment to aid log analysis. A log analysis cannot evaluate a set of logs properly without information on the local geology. Logs do not have a unique response, so it is necessary to combine more methods. And the limitation of logging measurements, which should be considered, is the borehole environment (diameter, mud, dimension of a probe, temperature, pressure, velocity of measurement). High technology and sophisticated interpretation procedures can overcome these limitations.

Principles

Well logging uses the principles of almost all methods in geophysical surface surveys: electrical, nuclear, seismic, geothermal, gravity, magnetic, and electromagnetic and additionally some procedures particular to drilling activity. The latter involve measurement of borehole diameter, bearing and deviation of the borehole from vertical, the strike and dip of beds, and the direction and velocity of fluid moving within a borehole. The instruments and measurements have to be adapted for the special conditions of the subsurface, particularly the confined space of a borehole, where they also have to overcome the alterations produced in the surrounding formation by the drilling. The drilled holes occur from a few meters depth for engineering purposes, to over 10 km for the crust at depth investigation. Most important are those for hydrocarbon exploration and extraction, which commonly reach depths of a few kilometers. The boreholes can be vertical, oblique, even horizontal and geophysical measurement can be also carried out between holes or between hole and the surface: nearwell and crosswell reflection imaging and tomography.

The variation of a property down a borehole is recorded against depth as a log. Most logs are run by lowering the tool (measuring device) on a cable, often called wireline. In some situations, especially if the borehole is deviated far from the vertical, or may be unstable, the tool is placed in a modified section of drill pipe, called a collar, and lowered into a hole at or near the end of the drilling string.

Many geophysical logging techniques were developed in the petroleum industry, which is the most important application in the exploration, evaluation, and production of oil and gas, by providing information on porosity, permeability, fluid content, and saturation of the formations penetrated by a borehole, but logging methods have also been applied in holes drilled for other purposes. Logging for uranium and coal is routinely used because it is relatively easy to identify and evaluate uranium and coal beds for their quality and thickness. Evergrowing applications of logs can be observed in water wells for evaluation of porosity and/or fractures, hydraulic parameters and water quality and groundwater dynamics. Shallow holes drilled for the characterization and remediation of contaminants has attracted some new logging techniques. Metal-mining applications continue to rely on the acquisition of core because borehole elemental assay methods have only been developed for a few specific cases. Core is also required for civil engineering (geotechnical) investigations: holes are generally shallow and core makes use of mechanical testing, whereas logging determines rock quality, namely, fractures under in situ conditions. Subsurface temperature measurements serve as critical input to many fields of engineering, exploration, and research such as gas and fluid production engineering, in well completions, in the exploration for hydrocarbons and ore minerals and for high-temperature geothermal resources as well, for testing hypotheses concerning the evolution of the Earth's crust and tectonic processes and for corrections of many temperature-sensitive borehole measurements. Various deep boreholes have been drilled for scientific purposes. Logging technology facilitates data generation for special geological studies concerning sedimentology and stratigraphic correlation, physical properties, mineralogy and geochemistry, fracture and stress, etc.

Instrumentation

Geophysical logging equipment appears complex, and the variety of instruments in use is very large. Any basic measuring system (measuring a natural physical field) consists of a sensor, signal conditioners, and recorders. Logging probes, also called sondes or tools, enclose the sensors, electronics for transmitting and receiving signals, and power supplies. Often there is an isolated artificial signal source in the lower part of the probe, which prevents the direct flow of the signal between source and sensor(s), so that the signal has to go through the rock surrounding the well. The probes (must be watertight and resistant to a high pressure and temperature) are connected to a cable by a cable head screwed onto the top of the probe. Some electric- and acoustic-logging devices are flexible; most are rigid. Probes vary in diameter from 25 mm to 150 mm. The probes are either axially symmetric (centralized) or use bowsprings or

springloaded arms to force the probe sensors pad or pads against the borehole wall (side collimation). Some tool arms may be hydraulically driven. All producers publish temperature, pressure, and diameter specifications for their sondes. Because the diameter is limited and much components must be installed in the sonde, in some cases sondes are very long (some meters) even if a large distance between a source and detector is not required. Usually, in deep holes, the probes are stacked to obtain multiple measurements for economical reasons. Measurements are usually made with the probe pulled upward by a winch fitted with a depth counter to insure steady tension on the logging cable when data are recorded. This results in more uniform speed and more accurate depth determination.

The most recent logging systems are fully digital, with control of the logging equipment implemented from a computer keyboard. Logs are displayed by the computer, and a field record is obtained from a printer. In logging of oil or gas wells, the measured data are telemetered to a computation center where they are promptly evaluated automatically.

The well-log equipments are mounted on vehicle chassis, lighter ones (with cable length ≤ 500 m) on minibus chassis, while the larger ones (with cable length 1,000–3,000 m) are truck-mounted and those for logging deep wells (to a depth over a 5,000 m) are mounted on heavy-duty trucks. In equipments of medium and large size, the winches are driven by the vehicle motors, in light equipments by separate electric motors or hydraulically. Portable devices are used for logging mine and engineering-geological boreholes of difficult access. They are provided with a logging cable up to 300 m long. The devices for logging in coal mines must be sealed to prevent electrically detonated explosions.

The most widely utilized logging methods are summarized in Table 1. The principles and applications of quoted methods in the Table 1 are explained at length in literature (Serra 2007; Serra and Serra 2004; Hearst et al. 2000; Asquith and Gibbon 1982; Keys 1997; Chapellier 1992; Schlumberger 1987/1989; Serra 1986; Rider 1986; Desbrandes 1985; Serra 1984; Pirson 1977, etc.)

Fundamentals of Log Analysis

The process of log analysis for a project can be simplified into several basic steps:

- Data processing, including depth matching and meeting all logs and other data from a single well and editing and smoothing the data set
- Correcting borehole effects and other errors
- Converting log measurements to geologic parameters of interest; this is best done with calibration data for each probe

Geophysical Well Logging, Table 1 The most commonly used logs

Type of log	Potential uses	Borehole conditions required	Limitations
Spontaneous potential SP	Lithology, correlation, water quality	Uncased, mud filled only	Needs contrast in solutes in borehole versus formation
Normal and/or lateral resistivity logs (non focused log), Ra	Lithology, correlation, water quality	Uncased, fluid filled only	Influenced by fluid resistivity and bed boundaries
Conductively focused-current logs, LL micro-focused logs, MLL	Lithology, correlation, water quality, monitoring formation fluid conductivity	Uncased, fluid filled only	Removes some but not all fluid and bed boundary effects
Inductively focused-current logs IL	Lithology, correlation, water quality, monitoring formation fluid conductivity	Uncased or cased with PVC or fiberglass, air or fluid filled	Poor response in massive resistive formations
Gamma-ray log GR spectral GR	Lithology, correlation	Most conditions	Unusual lithology interpretations in glauconite, arkose and phosphate sands
Gamma-gamma log GGL-D	Bulk density, porosity, moisture, lithology, correlation, well construction	Wide range	Mineralogy may influence calibration through Z effect
X-ray fluorescence log XRF	Elemental composition of ores	Slim uncased holes, constant diameter, pure water or dry	Very short radius of investigation, mineralogy affects the sensibility and accuracy
Neutron log NNL pulsed neutron porosity logging	Saturated porosity, moisture, lithology, correlation	Wide range, preferably in slim holes, fresh or brackish fluid filled	Ineffective porosity if clay minerals are included in total porosity
Spectroscopy of neutron-induced γ -rays	Mineralogy from elemental analysis	Wide range	Mineralogy may influence calibration
Nuclear magnetic resonance logging NMR	Amount of free fluids in the reservoir rocks	Uncased	Occurrence of magnetic minerals
Elastic wave propagation log (acoustic log) AL	Saturated porosity, lithology, correlation	Uncased, fluid filled only	Measures primary or matrix porosity rather than total porosity, soft formations
Cement bond log CBL	Fluid content differentiation, bonding of casing	Uncased or cased, fluid filled only	Response gives a circumferential average of bonding, may not detect channels
Acoustic televiewer AT	Character and orientation of fractures, solution openings, and bedding	Uncased, fluid filled, water or mud	Fracture interpretation may be affected by drilling damage to borehole wall
Borehole television BTV	Well construction, secondary porosity, lost objects	Uncased or cased, air or clear fluid	No information in opaque fluid, dark mineral bands mimic fractures
Caliper log CL	Borehole diameter, log correction, well construction, fractures, lithology	Most conditions	Probe performance often affected by borehole deviation
Temperature log TM	Fluid movement in the borehole and/or behind casing, gas inflow, heat flux determination	Water filled	Affected by disturbance to fluid column by probe motion
Fluid conductivity log FRL	Fluid movement in the borehole	Water filled	Affected by disturbance to fluid column by probe motion
Flowmeter FM	Vertical fluid movement	Fluid filled	Spurious results may be caused by convection, or by movement of fluid in annulus behind screens
Dipmeter and borehole image technologies	Dip of strata, features of structural geology	Uncased, fluid filled only	
Clinometer	Orientation of the dip log tool, deviation of the hole from vertical	Non metal casing, wide range	
Well completion methods	Well construction, numerous techniques for checking casing and completion materials, borehole deviation, etc.	All conditions	Labor and equipment intensive; completions may be irreversible and often depend on the specific interpretation

- Combining logs and other data from all wells on a project, so that the data can be extrapolated laterally in cross sections or on maps
- Writing a report describing the analytical procedures and results from the logs

The analysis of log data by computer offers a number of time-saving advantages: a large mass of data can be collated and displayed; logs can be corrected and replotted; scales can be changed, smoothing and filtering operations can be carried out; cross plots can be made between different kinds of logs

and core data and calibration curves; correlation functions and rations can be plotted, as well as cross sections and isopach maps. An excellent introduction into this matter is presented by Doveton (1994).

Cross Plots

Because valuable quantities can only be deduced from two or more physical properties, a number of logs are run; often several that will function together are combined in a single tool. Frequently used interpretation technique for more reliable estimation of resulting data is called cross plots. Fertl (1981) gives a good overview of the crossplot technique. The basic procedure is to plot log data for a given depth interval in a space defined by two log parameters. That is, one plots all pairs of observed values of neutron versus acoustic or density parameters, or density versus acoustic. Often, at each point in the plane of coordinate system corresponding to a measured pair of values, one plots a digit representing the number of times that pairs of values occur in the interval. Sometimes, the value of a third variable, such as the gamma-ray log, is measured at the same depth interval as the pair of data being crossplotted or is indicated by a color at the point in space; that is called a z-plot. This is particularly convenient in more complex lithologies.

Applications of Geophysical Well Logging

In the Oil Industry

The *spontaneous potential (SP) log* represents the measurements of the naturally occurring potential difference between two electrodes: one is movable in the well, the other is fixed (grounded) on the surface. It is measured in millivolts. Electric currents arising primarily from electrochemical factors within the borehole create the SP log response. These electrochemical factors are brought about by differences in salinities between mud filtrate (R_{mf}) and formation water resistivity (R_w) within permeable beds. Because a conductive fluid is needed in the borehole for the SP log to operate, it cannot be used in nonconductive (i.e., oil-based) drilling muds. The concept of static spontaneous potential (SSP) is important because SSP represents the maximum SP that a thick, shale-free, porous, and permeable formation can have for a given ratio between R_{mf}/R_w . SSP is determined by formula $SSP = -K \cdot \log(R_{mf}/R_w)$ [here R_{mf} is derived from the resistivity of mud, which is measured in the laboratory on a sample, while K has a value that depends on the temperature, it is 71 at the typical temperature of 25 °C] or chart and is a necessary element for determining accurate values of R_w and volume of shale. The record of SP shows permeable beds and their boundaries

and determines formation water resistivity and also volume of shale in permeable beds.

The *resistivity log* is used to determine the fraction of pore space that is occupied by water, called the water saturation, S_w (the fraction that is hydrocarbons $S_{hc} = 1 - S_w$). Because the rock's matrix or grains are commonly nonconductive, the ability of the rock to transmit a current is almost entirely a function of water in pores. Hydrocarbons are also nonconductive; therefore, as the hydrocarbon saturation of the pores increases, the rock's resistivity also increases. The most simple (standard) form of resistivity logging requires three electrodes that are lowered into a borehole, usually two current electrodes (a pair) A, B, and one measuring electrode M. The measuring electrode N is placed on the surface. The electrodes that are lowered into the borehole consist of lead rings fastened to the lower part of the cable or bar. Such an arrangement of electrodes is known as the resistivity logging probe. The contact between electrodes and formation is made through mud, which therefore must be conducting. The resulting curve is called apparent resistivity R_a . The true resistivity R_t would be measured by this simple sonde only in ideal case of homogeneous isotropic rock environment, which case in the borehole does not exist. The shape of resistivity curves obtained by logging is largely controlled by the configuration of electrodes. There are two basic types of simple resistivity probes, that is, *normal and lateral probes*. Normal probes have a distance between unpaired electrodes far smaller than between paired electrodes and represent the classical way of measurement. Measuring a set of R_a curves with different spacing is required to obtain a plot of values of R_a versus probe spacing. Connecting them by a line, we can correlate in this way obtained curves with theoretical curves (master curves) and thus to determine the true resistivity of the layer investigated, the resistivity and the diameter of the invaded zone. Since this process is extremely laborious, a method was sought which would replace this classic resistivity measurement and enable the true resistivity of rocks to be determined in a simpler way.

Research led to the development of a combination tool, known as laterologs, which consist of a central electrode and symmetrical placed other (shielding) electrodes. They have great advantage as the registered R_a values are closed to the true resistivity (Hearst et al. 2000; Schlumberger 1989; Serra 1986). Examples are the microlog, microlaterolog, proximity log, and induction log.

The *radioactivity logs* involve the use of radioactivity to identify lithologies and to help deduce density and porosity, particularly when a hole is cased because they will function with steel case in place. The simple *natural gamma ray-log* responds to total natural gamma ray activity of the surroundings rocks in the borehole, which is due mainly to potassium (K), thorium (Th), and uranium (U, resp. Ra). Of lithologies commonly present, usually shales have the highest activity;

sands are intermediate; limestones, dolomite, and quartz are low; while anhydrite, salt, coal, and chert are least active. Occasionally, potash beds, and accumulations of radioactive ores or minerals with higher activity than shales may be encountered. Although the gamma ray activity of shales varies widely on worldwide basis, it tends to be constant in a particular field. It is therefore used to estimate shale content, assuming the maximum value on the log means 100% shale and the minimum value means no shale. The *spectral gamma ray log* records separately the activities of K, Th, and U, so allowing more precise identification of shales, for these differ from other rocks in their relative proportions of the three elements. The *gamma–gamma or formation density log* (GG-D) has a strong source of gamma rays (mostly ^{137}Cs) at one end of the probe, at the other is a detector of the gamma rays that is shielded so that it cannot receive rays directly from the source, so only gamma rays that results from scattering from the surrounding rock are counted. The *neutron–neutron log* (NNL) is a record of the neutron flux after its passing from a source in the probe through a formation continuous with the borehole to the detector(s). The tool is equipped with a radioactive source that emits fast neutrons. Neutrons travelling through the formation only slow down significantly when they collide with atoms of a similar mass, that is, hydrogen atoms. That is why the measured value of NNL corresponds to the content of hydrogen (not only as its part of water or oil, but independently in the form of hydrogen occurrence in some minerals), referred to as hydrogen index. Other varieties of neutron–neutron log can be used, interrelated with application of different i) sources such as plutonium/beryllium or americium/beryllium or californium sources using neutron accelerators working in pulse regime and ii) detectors besides neutron tubes for epithermal and thermal neutrons using spectral detection of gamma rays produced as a result of few usual interactions of neutrons with formation (nonelastic collisions, neutron absorption, activation).

The *sonic log* measures a record of the elastic waves velocity versus depth in a borehole (see ► “[Seismic Properties of Rocks](#)”). The most simple tool design is single-transmitter tool, which commonly has a radial piezometric, electrostrictive, or magnetostrictive transducer placed along the axis of an acoustic tool. Receivers are mounted in much the same way. The borehole fluid must be a liquid for most tools to function. Care must be taken to acoustically isolate the transmitter from the receiver so signals are not transmitted through the tool (compare with *Seismic instrumentation*). This measuring system fails if the tool is not parallel to the borehole wall or if there are increases in hole diameter. To solve those problems, the *compensated acoustic log* was developed. It has two transmitters at each end, and for each transmitter there are two receivers positioned far enough along the tool that the first arrivals at both are rays refracted from the wall of the borehole. The choice of tool

frequency is critically important for the generation of useful acoustic logs. High frequency and short wavelength are characterized by detailed spatial resolution and strong attenuation. Low frequency and long wavelength are characterized by poor spatial resolution but low attenuation. Careful study of the effects of frequency on acoustic logging indicates that the most important requirement for logging tool performance is excitation of a single mode. Hearst et al. (2000) find that the most commonly used acoustic-logging frequencies (10–20 kHz) correspond with the source band most likely to excite the single fundamental pair of P and S peaks under typical logging conditions for 15–25 cm diameter boreholes. There are many variations of the continuous velocity log, but all rely more or less on the same principle, though the number and type of sources and receivers are variable. The advent of compact downhole electronics controlled by powerful computers in the logging truck has offered the collection of digital waveforms from logging tools consisting of many receivers. Thus, more information than just the first arrival can be presented, and several methods of presenting the information have been developed: the full-wave display, variable-intensity display. It is now common practice to record the entire waveform digitally for later processing (full-wave acoustic logging). Tool using this mode of acoustic propagation measure both the velocity and the amplitude of the various components of the full acoustic waveform, that is, compressional, shear, and tube (Stoneley) waves (Paillet et al. 1992; Chen 1989). Advances in characterization of full-waveform data facilitate fracture detection and evaluation, permeability measurement, and well completion. The measured data by continuous velocity log can help identify lithologies although the main application is to estimate the porosity. Other developments in acoustic logging are depicted in publication of Prenskey (1994): *reflexion (Pulse-echo) tool* which employs ultrasonic pulse-echo transducers (borehole-televue type) that measure signal velocity and amplitude and have application in both open and cased hole. Further advances in acoustic logging are improvements in techniques such as *Downhole seismic*, *Wellbore resonance*, *Behind-pipe flow*, etc.

The *temperature log* provides the values of temperature of fluids in a borehole (which is not necessarily in thermal equilibrium with the formation temperature) with depth (in $^{\circ}\text{C}$) or the temperature increment over a constant distance, that is, the temperature gradient (in $^{\circ}\text{C}.\text{m}^{-1}$). The instruments used are thermometers and differential thermometers. As a measuring element, temperature-dependent resistors are used. They are located in the probe so as to be in contact with the fluid with their entire surface, if possible, and to be simultaneously thermally insulated from the body of the measuring probe. The time constant of the device is thus reduced to a minimum. There are two types of temperature-dependent resistors: *thermally positive* (metal wires, e.g., platinum, copper, etc.) and *thermally negative* semiconductor

materials (thermistors). These thermally negative materials exhibit substantially higher sensitivity (by as much as 10 times) than the thermally positive materials, but their drawback is that their resistance varies with temperature nonlinearly (in contrast to metals). The temperature sensor independent of its material is usually inserted in a Wheatstone bridge so that temperature-dependent resistor is located in one branch of the bridge, and remaining three branches consist of resistors independent of temperature. For calibration, the logging thermometers are put into a water bath whose temperature is changed gradually and measured as accurately as possible. Desired accuracy is of the order of 0.01 °C, the effective accuracy of commercial temperature log is 0.5 °C. Very often, the temperature is recorded during the lowering of the probe so as to meet a thermal field with the minimum possible disturbance. The application of borehole-temperature data can be grouped in two broad categories: engineering uses and scientific uses (Prensky 1992). Engineering uses incorporate: (1) correction of resistivity logs because temperature normally increases with depth and resistivity is a function of temperature (and salinity); (2) reservoir engineering: temperature is required for calculations of hydrocarbon recovery factors, including pressure–volume–temperature relationships and gas–oil ratios; (3) well completion and production logging: this issue includes the production of hydrocarbons and geothermal energy, location of top of casing cement (owing an exothermic reaction of setting cement producing an obvious temperature anomaly), designing cement slurries, detecting channels in the cement, Fluid flow – temperature anomalies are used for identifying the depth of fluid and gas entry or exit, detection of casing leaks and intervals of lost circulation, fluid injection – the contrast in temperature between injected fluid and formation fluids can identify zones of fractures.

Scientific uses are based on heat-flow measurements in boreholes, which are made by combining sets of temperature measurements under a steady temperature regime and thermal conductivity data, following the formula $Q = K (dT/dz)$, where Q is heat flow, K is thermal conductivity (known from literature for a given lithology or measured in laboratory), and T is temperature at depth z (when the temperature of mud has equalized with the temperature of the formation). Temperature in a borehole also generally changes with time as it returns toward equilibrium after the disturbance caused by drilling, which can take long time and may range from a few days for a shallow (100–150 m) air-drilled hole to several months for deep mud-drilled oilwells. The heat-flow knowledge contributes to solving a lot of scientific work, such as study of the Earth's evolution, stratigraphic correlation (changes in thermal gradient may correspond to lithology variations), basin analysis and modeling, detection of zones of overpressuring, detecting of regional aquifer flow, exploration for geothermal reservoir, etc.

Borehole imaging technologies are based on three types of sensors: electrical, ultrasonic, and optical. The *dipmeter* can also be considered a form of imaging. The dipmeter is used to determine the dip angle and dip direction of planar features intercepted by the borehole.

Indirect-Imaging Technologies: Acoustic and Electrical

The electrical scanning tools rely on a resistivity contrast in the formation to obtain an image and thus limited to holes with conductive mud. Acoustic-imaging tools use a rotating, focused, ultrasonic transducer to measure reflectivity times and amplitude of the pulse-echo from the borehole wall or from the casing. Acoustic amplitude is sensitive to borehole irregularities, thus enabling determination of borehole shape, that is, borehole caliper. Prensky (1994) gives an excellent summary of the literature as regards the possibilities of these borehole imaging tools for identification and analysis of natural and induced fractures; borehole breakouts; thin beds; geologic structure, such as strike, dip, and faults; identification of sedimentary features; interpretation of depositional environment; and evaluation of casing corrosion.

Direct Imaging Technology: *Borehole video* is a wireline tool containing a miniature television camera and light source to obtain high-resolution, real-time visual images of the borehole or tubulars, in both air- or fluid-filled boreholes. The recent introduction of fiber-optic-based systems offers reduction in tool diameter and operation in greater depths. Applications include inspection of casing, tubing and perforations, detection of produced fluid entry, fracture deification, etc.

The *caliper logs* facilitate measurement of the true size and shape of a drilled hole. Most caliper tools are mechanical. The mechanical tool consists of several arms, which are pushed out against the wall of the hole by springs or hydraulic pressure; their extent is converted by an electromechanical device into an electrical signal suitable for recording (proportional to real diameter). Most independent calipers have three or four arms; some have as many as six. The diameter of the borehole is necessary to be known to introduce corrections in quantitative interpretation in almost all methods measured in the boreholes; to calculate the amount of cement needed to fix the casing; to give lithologic information, because washouts are indicative of formation properties – weak formations will tend to wash out, strong ones will not. Caliper logs can also give evidence of the presence of fractures.

The simplest relation between electrical conductivity and formation properties is given by an empirical relation between formation factor F , defined as the ratio of the resistivity of a rock fully saturated by water R_0 to the resistivity of the water R_w with which the rock medium is saturated, and porosity Φ of clean sands (known as Archie's law): $F = R_0/R_w = a/\Phi^m$, where the coefficient a 'and the exponent m ' (cementation factor) can be determined independently from laboratory measurements on core samples and are usually consistent within a lithologic unit. The Archie's formula has some

limitations dealing with conductivity of pore space, which is frequently discussed in literature, for example in Hearst et al. 2000. *Dielectric log* is an electromagnetic method using high frequencies, when dielectric properties begin to dominate the propagation characteristics of electromagnetic waves. The presence of water continues to govern the tool response in this high-frequency regime (100 kHz and greater) because the dielectric permittivity of water is significantly greater than that of most earth materials. *Pulsed neutron logging* measures the rate of decay of thermal neutrons in the interval between two pulses of a neutron generator. *Nuclear magnetic resonance logging* (NMR) has been available for many years, since 1960s, but the literature on the applications of borehole NMR has grown very rapidly in the 1990s, and is constantly increasing. Originally, the method is based on the measurement of nuclear spin and magnetic moment of a hydrogen nucleus providing data of the free fluid index – how large a volume of fluid can be obtained from the rock by pumping, and the character of the fluid at the selected depths. The total signal is proportional to the total number of protons present in both the free and bound fluid. NMR measures proton spin–lattice (longitudinal, T1) and spin–spin (transverse, T2) relaxation times; these relaxation times are proportional to pore size and to bound (clays) and free (pore) fluids. In petrophysical terms, these parameters provide information for quantitative determination of permeability, pore-size distribution lithology in reservoir rocks. Kenyon (1997) is an excellent summary of the application of NMR to petroleum industry.

Porosity derived from logs shows summary in the Table 2.

Hydrogeologic Applications

Geophysical well logs in water wells can be used to determine lithologic parameters with the aim to evaluate quality and geometry of aquifer system, both with intergranular porosity

and fracture and estimate the quality and amount of contained water in the surroundings rocks. In addition to the lithologic parameters, a second important category of information that can be derived from well logs includes data on the character and movement of water in the borehole and the formation. Characteristics of fluids in the well bore can be measured directly, but the data on formation fluids must be inferred from logs. *Logs of the conductivity and temperature* of fluid in the borehole can be related to formation-fluid characteristics, provided that the well has had time to attain chemical and thermal equilibrium with the groundwater reservoir, that an adequate hydraulic connection exists between the hole and the rocks penetrated, and that the inhole flow does not disturb these conditions. *Flowmeters* (Schlumberger 1993) are probes designed to measure groundwater flow rates along boreholes under ambient and forced gradient (during pump-test) conditions. Impellor flowmeters (Hill 1990; Keys and Sullivan 1979) require a significant velocity to rotate impellor blades, so that this probe cannot measure velocities less than about 10^{-1} m/s. Heat pulse (Hess 1986) and electromagnetic (Molz et al. 1994) flowmeters can detect velocities as low as 10^{-3} m/s.

Techniques based on *time sequence measurements of flow logs* are applied only in clean wells, where mud has been replaced by water and the filter cake does not affect aquifer permeability in the vicinity of the borehole. Under these conditions, changes in the physical properties of the borehole fluids under ambient or stressed conditions reflect the properties of the formation and the water contained in the formation. Various properties of water in boreholes, such as the conductivity, temperature, transparency, and/or radioactivity (using tracers) as a function of depth, may be used in this fluid column logging method (Chapellier 1992; Kobr et al. 2005). Many of these properties can be measured using conventional borehole logging equipment. Log-derived hydraulic parameters, such as hydraulic conductivities or transmissivities can be obtained from both flowmeter analysis and time sequence

Geophysical Well Logging, Table 2 Summary of porosity derived from logs

Log	Property measured	Response to the type of porosity	Extraneous effects	Borehole requirements
Gamma-gamma	Electron density	Total porosity, best for high porosity	Matrix, salinity, water saturation, well construction	Wet or dry, cased or open
Neutron	Hydrogen content	Total porosity, best for low porosity	Bound water, matrix chemistry, salinity, water saturation	Wet or dry, cased or open
Acoustic velocity	Average P-wave velocity	Total porosity, only primary and intergranular	Cycle skipping, poor in high-porosity sediments	Fluid filled and open, high pressure
Resistivity	Pore fluid and interconnected porosity	Effective porosity both primary and secondary	Pore shape, fluid chemistry, water saturation	Open or with perforated PVC casing
Gravity logging	Bulk density	Total porosity	Stationary measurement	Deep reading, >50 ft. (18 m)
Nuclear magnetic resonance	Relaxation time of protons	Amount of fluid in pores larger than some minimum	Bound water, very small pores, clay and magnetic minerals	Open hole

of fluid logs. The last named method is also used to study water flow in the rock medium. Movement of the groundwater flow in sandy aquifers is oriented in the direction of the hydraulic velocity, by the hydraulic conductivity and the azimuth (direction) of the flow. Properly interpreted borehole fluid log can be used to locate zones where water enters and/or leaves the well bore, to estimate the specific yields of these zones and all parameters cited above. Also, this methodology is advantageous in contamination studies, to check the quality of well completion and in shallow boreholes for engineering geology (Hess 1986; Tsung et al. 1990; Kelly and Mareš 1993; Mareš et al. 1994; Molz et al. 1994; Paillet and Crowder 1996; Keys 1997; Paillet 2000).

Mineral Exploration

Although boreholes are routinely cored to detect and quantify the presence of economic minerals, often the information is incomplete because of missing core, or misleading because of rapid lateral variation of the mineralization (hydrothermal veins). The depth of investigation may be increased by lowering down the hole closer to the ore bodies. The logging system is adapted to the conditions of a mineral exploration program (smaller holes as diameters – from 49–122 mm; as depths – often less than 100 m) using portable logging system with appropriate methodology. The physical properties of interest are density, average mass number, electrical conductivity, and magnetic susceptibility. For disseminated types of ores induced polarization method is useful. Sometimes, self potential method is also used. In this case, the spontaneous potential is of interest in connection with minerals that are electronic conductors, such as massive sulfides, magnetite, and graphite. If two boreholes are available at reasonable mutual distance a cross-hole tomographic survey can be carried out either with seismic or electromagnetic method. This later can map the conductivity distribution between boreholes in the exploration for minerals as well as in environmental and crustal studies (see ► “Instrumentation, EM”). The modern radioactive methods (X-ray fluorescence analysis, spectroscopy of neutron-induced γ -rays) enable implementation of elemental analysis of the rocks in situ conditions. Due to heavy expenses involved, these methods are not usually considered as the routine ones in mineral exploration. But in some special conditions they may be economic (for example, neutron activation in the borehole on fluorine can be used for calculation of reserves).

Civil Engineering, Rock Mechanics, and Environmental Preservation

Other well-logging applications for various geological studies can be found in literature (Deltombe and Schepers 2004;

Hurst et al. 1992; Hurst et al. 1990). Almost all methods discussed earlier can be applied, some modifications have been introduced. The most important methods for this reason are the acoustic methods: *sonic log*, *vertical seismic profiling*, *seismic tomography*. The main goal of this application is direct (in situ) determination of dynamic elastic properties because sonic logging and waveform analysis provide the means for obtaining continuous measurements of compression and shear velocities. More information can be found in Takahashi et al. (2006).

Summary

Geophysical logs are made by instruments in sondes, or tools, suspended mostly on a wire, with readings usually taken as they are pulled to the surface. Sondes often contain several instruments that can operate without mutual interference. The records of the variation of various quantities down boreholes are called logs, and are of both geophysical and non-geophysical quantities. Geophysical logs are often more valuable when combined than when used singly. Geophysical logging is not only cheaper than continuous coring but it provides information that cannot be obtained on cores, partly because of the alterations produced by the dribbling, and reduces the need for sampling.

Measurements of geophysical parameters in boreholes present the follows characteristics:

- Instruments have to be adapted for the dimensions of a borehole and usually to operate submerged in drilling mud.
- Measurements have to take into account the conditions (pressure, temperature, and technical conditions of the borehole) resulting from the drilling.

The most important application of well logging in the exploration, evaluation, and production of oil and gas, as well as other uses in different geological and engineering branches has been discussed.

Geothermal Heat Pumps

Ladislaus Rybach

Institute of Geophysics, ETH Zurich, Zurich, Switzerland

Definition

A geothermal heat pump (GHP) is a heating and/or cooling system that moves heat to or from the ground. It uses the earth as a heat source (in the winter) or a heat sink (in the summer). Geothermal heat pumps are also known by a variety of other names, including ground-source, geexchange, earth-coupled, earth energy, or water-source heat pumps. They can be designed and installed in sizes from a few thermal kW to several MW capacity (the latter in modular assemblage). Currently, GHPs represent the largest share in geothermal direct use and account mainly also for the global growth.

The Resource

Shallow geothermal resources (the heat content of rocks in the top few meters of the continental crust) represent a major and ubiquitous energy source. The earth as planet can afford to give off heat by a thermal power of 40 million MW, without cooling down. Without utilization, the terrestrial heat flow is lost to the atmosphere. In this case, the isotherms run parallel to the earth's surface (i.e., horizontal in flat terrain) and the heat flow lines are

Geothermal Heat Pumps, Fig. 1 Principle of geothermal heat extraction and production

perpendicular to them. If, instead, the heat flow can be captured, e.g., by a heat extraction device like a borehole heat exchanger (BHE) (see later), the isotherms are deformed and the heat flow lines can be diverted toward heat sinks (Fig. 1).

Geothermal Heat Pump (GHP) Technology

A new chapter in the history of geothermal applications in buildings opened with the advent of geothermal heat pumps. This technology enables space heating, cooling, and domestic warm water production with the same installation. The GHP application is now in the focus of private, public, and municipal interest (Banks 2008). Geothermal heat pumps (GHPs) are one of the fastest growing applications of renewable energy in the world and definitely the fastest growing segment in geothermal technology, in an increasing number of countries (Rybach 2005). GHP represent a rather new but already well-established technology, utilizing the immense renewable storage capacity of the ground. GHPs use the relatively constant temperature of the ground to provide space heating, cooling, and domestic hot water for homes, schools, factories, public buildings, and commercial buildings. The applicational size can vary from single-family homes with 1–2 borehole heat exchangers (BHEs) to large-scale complexes with hundreds of BHEs. The decentralized systems can be tailor-made, taking into account the local conditions. It is essential to employ proper installation design that takes into account meteorologic, ground property, and technical supply conditions. By these means, reliable long-term operation can be secured. Of the local conditions, the thermal conductivity of ground materials and the groundwater properties are of key importance.

There exist mainly two types of geothermal heat pumps (Fig. 2). In ground-coupled systems, a *closed loop* of plastic

pipe is placed in the ground, either horizontally at 1–2 m depth or vertically in a borehole down to 50–300 m depth. A water-antifreeze solution is circulated through the pipe. Thus, heat is collected from the ground in the winter and optionally heat is rejected to the ground in the summer. An *open loop* system uses groundwater or lake water directly as a heat source in a heat exchanger and then discharges it into another well, a stream, or lake, or even into the ground. The installation of horizontal coils needs relatively large surface area and extensive earthworks (digging the ground down to the level of coil layout); the prerequisite for extracting the heat of groundwater is the presence of a shallow water table. For these reasons, the most widespread technology of shallow heat extraction is by BHEs. Heat extraction is established by closed-circuit fluid circulation (a few m³/h of pure water or with an antifreeze additive) through the BHE and the evaporator side of the heat pump.

Three basic components make up a GHP system: (1) the heat extraction/storage part in the ground, (2) the central heat pump, and (3) the heat distributor/collector in the building (e.g., floor panel). The key component is the heat pump. In essence, heat pumps are nothing more than refrigeration units that can be reversed. In the heating mode, the efficiency is described by the coefficient of performance (COP) which is the heat output divided by the electrical energy input for the heat pump. Typically, this value lies between 3 and 4 (Rybach 2005). Except for larger, singular applications where gas-driven heat pumps are used, most heat pumps use electricity for their compressors. Therefore, GHPs are electricity consumers. The source of electricity varies from country to country; it would be elegant if the electricity to drive the GHP heat pumps would originate from renewable sources like solar, wind, or even geothermal! The principal components of a BHE-based GHP system are depicted in Fig. 3.

Heating and Cooling with GHPs

As mentioned above, GHP systems can provide space cooling also. In moderate climate, the ground below about 15 m depth is significantly colder than outside air in summer. Thus, a large geothermal store with favorable heat capacity is available where the heat can be exchanged (extracted from the building and deposited in summer, extracted from the ground store and supplied to the building in winter). The thermal capacity of the system depends, besides the volume, on the thermal and hydrogeologic characteristics of the installation site; these must be carefully considered in system dimensioning. In summer, most of the time the heat pump can be bypassed and the heat carrier fluid circulated through the ground by the BHEs and through the heating/cooling distribution (e.g., floor panels).

Geothermal Heat Pumps,

Fig. 2 Closed loop and open loop (groundwater) heat pump systems. The arrow indicates the most common system, with borehole heat exchangers (BHE). The heat pump (HP) is the red box in the house. (Modified from Lund et al. 2003)

Geothermal Heat Pumps, Fig. 3 Sketch of a GHP system with a single BHE. Horizontal/vertical arrows indicate circulation in the U-tube heat exchanger, oblique arrows indicate heat extraction from the ground (heating mode in winter). In summer, the oblique arrows are reversed; heat is extracted from the building and stored in the ground

By these means, the heat is collected from the building and deposited in the ground for extraction in the next winter (Lund et al. 2003).

Design, Costs

BHEs can be installed in nearly all kinds of geologic material. Design and installation must consider numerous influence factors. The sizing must consider the demand characteristics of the object to be supplied (size, extension; heating alone, or heating + domestic water, combined heating/cooling) as well as the local site conditions (climate, ground properties). The key ground property is the thermal conductivity of the ground surrounding the BHE. The higher the rock thermal

Geothermal Heat Pumps, Table 1 Borehole heat exchanger performance (single BHE, depth ≈ 150 m) in different rock types. (From Rybach 2001)

Rock type	Thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$)	Specific extraction rate (W per m)	Energy yield ($\text{kWh m}^{-1} \text{a}^{-1}$)
Hard rock	3.0	Max. 70	100–200
Unconsolidated rock, saturated	2.0	45–50	90
Unconsolidated rock, saturated	1.5	Max. 25	50

conductivity (W/m,K), the higher the specific heat extraction rate (W/m) and the energy yield (kWh/m,a) per unit BHE length (see Table 1). The installation and operation of a BHE/HP system needs installation and running costs. BHE drilling and installation costs amount to about 50 US\$ per meter in the USA and about 70 € per meter length in Europe. The operational cost is significantly less than with fossil-fueled systems. Currently, the price of heat and cold provided by GHP systems is comparable with conventional systems; GHP installation cost payback (the period of years before the savings in annual operating costs exceed the initial premium of an installation) ranges from 4 to 10 years, depending on the size and complexity of the system.

GHPs represent by far the fastest growing market in geothermal development and are also one of the fastest growing renewable technologies: the annual growth rate of globally installed capacities between 1995 and 2015 was 20% (Rybach and Sanner 2017).

Licensing, Environmental Benefits

In general, GHP installation needs permits. In most countries, the water protection agencies (local, regional, national) are providing permits. Regulation varies from country to country, in some cases even within the same country. Usually, some standard forms need to be filled and submitted. It is common

practice that in groundwater protection areas, the installation of GHP systems is limited or forbidden.

GHPs operate with little or no greenhouse gas (GHG) emissions since no burning processes are involved. GHPs driven by fossil-fueled electricity reduce the CO₂ emission by at least 50% compared with fossil-fuel-fired boilers. If the electricity that drives the geothermal heat pump is produced from a renewable energy source like hydropower or geothermal energy, the emission savings are up to 100%. Reducing current CO₂ emissions is the central option in all the efforts to mitigate global warming. Here, a clear distinction must be made between actual emission reduction and merely avoidance of additional emission: by new GHPs, only additional CO₂ emission can be avoided (“saving”), not a reduction of actual emissions. When GHPs are installed in refurbishment (to replace fossil-fueled systems), actual emission reduction can be achieved. Emission reduction is also evident when electric heater/cooler installations, driven by fossil-based electricity, are replaced by GHP systems.

Applications, Development Trends

There is a growing number of successful examples of GHP applications, for all kinds of buildings of highly varying sizes. The largest installation currently under construction is the geothermal store at the Bell State University (Indiana, USA) campus, with 4,100 BHEs, each 120 m deep (IGSHPA 2009). Several international organizations cover and/or promote the applications of GHPs. Here, only a few links are provided.

- International Ground Source Heat Pump Association (IGSHPA) <http://www.igshpa.okstate.edu/>
- Geothermal Heat Pump Consortium (GHPC) <http://www.geothermalheatpumpconsortium.org/>
- International Energy Agency Heat Pump Centre <http://www.heatpumpcentre.org/>
- European Heat Pump Association (EHPA) <http://www.ehpa.org/>

Besides, there are national associations active in many countries.

Most GHP systems operate with borehole heat exchangers (BHEs). In the early days of BHE applications, the boreholes have been drilled outside the objects to be served by the GHP installations. Nowadays, also dictated by the high prices of land, the boreholes are more and more located beneath the buildings to be erected.

Energy piles are now becoming increasingly popular. At many locations, the ground properties are such that load-

bearing rock formations occur only at some depth. Therefore, foundation piles need to be placed to secure firm standing of buildings. These piles can be equipped with heat exchanger pipes; the assemblage is then called “energy pile.” Special care must be taken to secure that the temperature changes caused by heat extraction and storage does not affect the pile/ground contact. A special handbook has been published in Switzerland that describes design, installation, and operation of energy pile systems (SIA 2005).

Summary

Currently, geothermal heat pumps (GHPs) represent the fastest growing branch in the utilization of geothermal energy. There are various factors that can lead to the successful dissemination of the GHP technology. Promoting factors are manifold: technical, economic, environmental awareness, governmental support, etc. The most important driving force is simply knowledge and know-how. Besides, various applications and wide-scale realizations, high-level quality assurance, and successful demonstration facilities are needed.

The use of GHP systems represents an important contribution of renewable energies to the mitigation of climatic warming: the increasing use of the environmentally friendly geothermal technology enables the saving of great amounts of fossil fuels, avoid corresponding CO₂ emissions and, in the case of the application of GHP systems in building renovation, it results in a significant emission reduction. It can be expected that GHP systems, along with other geothermal technologies (especially for power generation), will further increase the benefits to future generations.

Definition

Temperature changes at the Earth's surface diffuse slowly into the subsurface where they perturb the normal geothermal regime. The geothermal record of climate change utilizes precise temperature-depth measurements of these perturbed temperatures from boreholes to obtain a long-term, low-pass record of temperatures at the Earth's surface as interpreted using the one-dimensional heat diffusion equation.

Introduction

Because changes in temperature at the Earth's surface are transferred to the subsurface through the process of thermal diffusion, past changes in decadal and centennial surface temperature trends are now evident in subsurface temperatures. Thus, temperature-depth measurements in boreholes register not only the heat flowing out of the Earth but also transient departures from the background attributable to past surface temperature changes (e.g., Lachenbruch and Marshall 1986; Pollack and Chapman 1993; Pollack and Huang 2000; Beltrami 2002a; Harris and Chapman 2005). Identifying and interpreting these transient departures in terms of the past few hundred years of surface temperature change is now known as the geothermal method of climate reconstruction. Because thermal diffusion behaves as a low pass filter, such that high

frequency changes in surface temperature are attenuated more strongly and at shallower depths than longer-term changes, this method is most useful in identifying centennial scale climatic trends. The geothermal method of climate reconstruction has several benefits including (1) bypassing the empirical temperature calibration inherent with proxy records of climate change; (2) extending coverage to remote and widely dispersed continental sites where meteorological instrumental records are not available; and (3) establishing a surface baseline temperature prior to the Industrial Revolution when anthropogenic greenhouse gases started their unprecedented growth phase.

The Geothermal Method of Temperature Reconstruction

The geothermal method of temperature reconstruction is most easily understood in terms of the one-dimensional heat diffusion equation,

$$\frac{\partial T(z, t)}{\partial t} = \alpha \frac{\partial^2 T(z, t)}{\partial z^2}, \quad (1)$$

where T is temperature, z is depth, t is time, and α is thermal diffusivity. This equation shows how temporal variations in surface temperature lead to curvature in temperature-depth profiles. Time and depth are scaled nonlinearly through the thermal diffusivity such that a surface temperature change at time t prior to the present is largely captured within a depth, l , called the thermal length,

$$l = \sqrt{4\alpha t}. \quad (2)$$

Because the thermal diffusivity of rocks is about $1 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$, the majority of the past 100 years of surface temperature change is stored within the upper 150 m of the Earth; the majority of the last 1000 years of surface temperature change is captured in the uppermost 500 m. Careful analysis of curvature in the upper few hundred meters of a temperature-depth profile, therefore, can be used to reconstruct surface temperature change over the past millennium (e.g., Huang et al. 2000; Harris and Chapman 2001; Beltrami 2002b; Beltrami and Boulton 2004; Pollack and Smerdon 2004).

Useful analytical solutions to Eq. 1 for a temperature-depth profile resulting from simple functional changes of temperature at the Earth's surface include the following (Carslaw and Jaeger 1959; Lachenbruch and Marshall 1986; Chisholm and Chapman 1992):

- (a) single step ΔT change in surface temperature at time τ before present,

$$\Delta T(z) = \Delta T \operatorname{erfc}\left(\frac{z}{\sqrt{4\alpha\tau}}\right), \quad (3)$$

- (b) multiple step ΔT_i changes in surface temperature at respective times τ_i before present,

$$\Delta T(z) = \sum_{i=1}^n \Delta T_i \operatorname{erfc}\left(\frac{z}{\sqrt{4\alpha\tau_i}}\right), \quad (4)$$

- (c) a single ramp change in surface temperature starting at time τ before present and with amplitude ΔT when the temperature log is obtained,

$$\Delta T(z) = 4\Delta T i^2 \operatorname{erfc}\left(\frac{z}{\sqrt{4\alpha\tau}}\right), \quad (5)$$

where the complementary error function is denoted by erfc and $i^2 \operatorname{erfc}$ indicates the second integral of the complementary error function.

Interpretations of surface temperature change from the geothermal method of climate reconstruction are most confident when curvature in the temperature-depth profile can be shown to be transient and fully attributable to a changing surface temperature in the past. Because the Earth is not homogeneous, phenomena and processes other than a changing surface temperature can also cause curvature in temperature-depth profiles. Steady-state sources of curvature include variations in subsurface thermal conductivity, radioactive heat production, heat refraction due to topography, and differential solar insolation due to variations in slope and azimuth. Transient sources of curvature include changes in ground surface temperature in response to changes in surface air temperature (SAT), spatial changes in surface temperature around the borehole caused by temporal variations in albedo, non-isothermal groundwater flow, precipitation, and other microclimate effects (e.g., Beck 1982; Chisholm and Chapman 1992; Lewis and Wang 1992; Harris and Chapman 1995; Bartlett et al. 2004). Chisholm and Chapman (1992) and Harris and Chapman (1995) explore the magnitude of many of these effects quantitatively. While most studies of climate change inferred from borehole temperature profiles attempt to select sites that minimize these non-climatic sources of borehole temperature profile curvature, it is often difficult to partition curvature between steady-state and transient sources of curvature. Repeated temperature measurements in the same borehole can help improve the confidence in separating and interpreting steady-state and transient sources of curvature (e.g., Davis et al. 2010; Majorowicz et al. 2012).

Tutorial

Important elements of the geothermal method of climate reconstruction are illustrated in Fig. 1. First, consider a

ground surface temperature (GST) that is essentially constant in time (dashed line; Fig. 1a). In this case, the measured borehole profile has no transient curvature, and the surface temperature intercept is equal to the GST (Fig. 1b). However, if the GST is not constant, but fluctuating in some way such that there is a deviation from the mean GST, it will impart curvature to the subsurface according to Eq. 1 (Fig. 1b). For interpretations of climate change based on temperature profiles, one is interested in the departures from the background thermal regime. To highlight these departures, we compute reduced temperatures expressed as

$$T_r(z) = T_{obs}(z) - (T_o + \Gamma z), \quad (6)$$

where T_o is the reducing intercept and Γ is the reducing gradient. In Fig. 1c, the background gradient has been removed, making the anomalous temperature strikingly apparent. The transient nature of the anomaly is illustrated by measuring the borehole temperatures at several times. The three temperature-depth profiles marked I, II, and III in Fig. 1b, c were measured at three different times shown by the solid triangles in Fig. 1a. Cooling from 1915 to 1955 creates a negative transient in the 1955 log I. Surface warming since 1955 results in warming features in the temperature-depth logs II and III that propagate deeper with time. This example also illustrates the low pass smoothing of thermal diffusion. While trends in subsurface curvature can be related to trends in GST, individual annual means are not apparent. Further, the resolution of the magnitude of GST change is much better resolved than the timing of the change, consistent with the physics of diffusion (Chisholm and Chapman 1992).

Because SATs represent the gold standard of temperature change, and because climatic proxies such as tree rings are empirically calibrated to SATs, a final step is often taken whereby derived changes in GST are related to SATs. Many borehole temperature-depth profiles are located in areas where SAT records exist, and the combination of datasets offers additional information about surface temperature change. Techniques to compare or use borehole temperatures with surface records include overlaying a GST reconstruction on an appropriate SAT curve (e.g., Huang et al. 2000) or using an appropriate SAT curve as a forcing function and comparing the resulting transient temperature depth curve to a reduced temperature profile (e.g., Harris and Chapman 2001). In this second technique, the best fitting initial temperature, sometimes called the pre-observational mean (POM; Chisholm and Chapman 1992; Harris 2007), is found by minimizing the fit between the reduced temperatures and the synthetic transient calculated from the SAT time series. An obvious uncertainty in this step is the nature of coupling between air and ground temperatures. Regional comparisons at the centennial time scale generally show good agreement between changes in air and ground temperature (Huang et al. 2000; Harris and Chapman 2001; Beltrami 2002b; Pollack and Smerdon 2004;

Geothermal Record of Climate Change, Fig. 1 Basic aspects of the geothermal method of climate reconstruction. (a) An arbitrary time series of surface temperatures for the last century. Dashed line represents a climatic history with no temperature change. Triangles indicate times of borehole temperature logs illustrated in (b) and (c); log I in 1955, log II in 1975, and log III in 1998. The method asserts that changes in ground surface temperature are

manifested as transient departures from the background, steady-state thermal regime for which a constant temperature gradient facilitates the conduction of heat from the Earth's interior. (b) Temperature-depth profiles for times I, II, and III. The linear profile results from the zero change scenario in (a)—dashed line. (c) Reduced temperature-depth profiles with background removed at times I, II, and III

Pickler et al. 2018). Modeling studies using general circulation models allow comparisons between changes in air and ground temperatures at longer time scales and also suggest good agreement between these measures (Gonzales-Rouco et al. 2003, 2006, 2009; Garcia-Garcia et al. 2016). Questions regarding changes in the relationship between air and ground temperatures have prompted detailed investigations often in combination with other meteorological parameters (e.g., Smerdon et al. 2003, 2004, 2006; Bartlett et al. 2006; Chudinova et al. 2006; Stieglitz and Smerdon 2007; Cheng et al. 2010). These studies have found that variations in air and ground temperatures generally track each other over the time period of study.

A Global Geothermal Climate Change Database

An archive of borehole temperature profiles at 1012 sites (Huang et al. 2000) suitable for studying climate change has been compiled at the University of Michigan and the National Centers for Environmental Information of the National Oceanic and Atmospheric Administration. Individually the borehole temperature profiles exhibit many characteristics of the

Geothermal Record of Climate Change, Fig. 2 (a) The number of boreholes in the global climate borehole database with temperature observations to a given depth (shaded). (b) Temperature versus depth at times following a step change ΔT in surface temperature. Solid dots mark depths where the signal is 5% of the surface change

meteorological record of climate change: hemispheric scale variation, regional variation, local effects, and noise. Collectively, however, borehole temperatures show clear evidence of significant twentieth-century warming and a potential for inferring longer-term climate change (Huang et al. 2000). Figure 2a shows a histogram of the number of boreholes in the global climate borehole database with temperature observations to a given depth. Boreholes at all 1012 sites extend to at least 200 m depth, one criterion for inclusion in the archive. Half of the boreholes are deeper than 350 m but fewer than 10% extend more than 600 m into the subsurface. The depth distribution of boreholes is important because the depth of borehole temperature anomalies is related to the timing of surface temperature changes (Eq. 2), as shown in Fig. 2b. The resolution of borehole temperature measurements can

generally resolve a surface temperature signal that is greater than 5% of the surface temperature change. Figure 2b shows that to reconstruct past surface temperature adequately for the entirety of the last millennium, one must collect temperature-depth measurements down to at least 500 m depth. In practice these records must be deeper than 500 m so that the background thermal gradient and surface temperature intercept can be adequately estimated (Eq. 6).

Temperature-Depth Profiles

An ensemble of climatically perturbed temperature-depth profiles from India (Roy et al. 2002) is shown in Fig. 3a. The boreholes are from the north-central climatic province of

Geothermal Record of Climate Change, Fig. 3

(a) Plots of temperature-depth data (open circles) obtained at 10 selected sites from the north-central climatic province of the Indian peninsula. (Modified from Roy et al. 2002). The background temperature profiles (solid lines) are obtained by fitting a line just below the curved upper portion in each temperature-depth profile. Temperatures below 500 m are not displayed. (b) Reduced temperature profiles (open circles) for the 10 boreholes shown in (a). Each profile is offset to avoid overlap and plotted relative to zero reduced temperature (dashed line). Solid lines show the best fitting ramp models for the reduced temperature profiles. The magnitude and onset time of the ramp model are shown at the top of the profiles. (See Roy et al. (2002) for more details)

India. The first-order effect shown in these profiles is the general increase in temperature with depth, consistent with an upward flux of heat toward the Earth's surface. The deepest part of the borehole temperature profiles has a constant background thermal gradient. Figure 3b shows the reduced temperature profiles for these sites after the background gradient and surface temperature intercept have been removed (Eq. 6), illustrating the transient temperature departures in the uppermost 200 m of the boreholes. The transient departure from a steady-state background signal is most consistent with a ramp change of amplitude -0.3 to 3.8 °C starting 27 to 295 years ago. This example is notable because it shows the predominantly warming signal shown in ground temperatures consistent with surface temperature warming over the past two centuries, as well as the site-specific climatic conditions recorded in subsurface temperatures.

Repeat Temperature Logs

The regional analysis of Davis et al. (2010) employed multiple repeat temperature-depth profiles from three individual boreholes in northwestern Utah over nearly 30 years to provide observational constraints for understanding the relationship between ground and air temperatures. A key part of the study was to calculate and compare synthetic temperature profiles from nearby SAT records to the observed temperature profiles. The synthetic profiles closely fit observed temperature-depth profiles and match both the amplitude and pattern of subsurface transient changes. Further, forward modeled ground temperatures and differences between temperature logs isolate transient variations and indicate that the observed profiles can be ascribed to changes in GST (Davis et al. 2010). Such observations of transient temperatures in boreholes offer strong support for using GST histories to complement SAT data and multi-proxy reconstructions in climate change studies.

Temperature Reconstruction Analysis

Several groups have used boreholes to analyze past temperatures on both regional (e.g., Lachenbruch and Marshall 1986; Beltrami and Mareschal 1991; Chisholm and Chapman 1992; Harris and Chapman 1995; Roy et al. 2002; Davis et al. 2010; Pickler et al. 2018) and global (e.g., Huang et al. 2000; Harris and Chapman 2001; Beltrami 2002b) scales. The temperature reconstruction of Huang et al. (2000) utilized the global database and a Bayesian estimation technique, similar to the functional space inversion of Shen and Beck (1991). The method parameterized the reconstruction into century-long rates over the past 500 years, resulting in a 1.1 °C increase over the entire period (Huang et al. 2000). Further analysis of this dataset partitioned the borehole into both hemisphere and

Geothermal Record of Climate Change, Fig. 4 (Top) Northern Hemisphere reduced temperature profiles from Harris and Chapman (2001) and Roy et al. (2002). Lines represent 509 profiles whose locations are shown on the map (bottom). Bold line shows average reduced temperature profile. (Figure modified from Harris and Chapman (2001))

continental reconstructions. Huang et al. (2000) found that warming was greatest in the Northern Hemisphere, and greatest in the twentieth century.

Another analysis used a Northern Hemisphere subset of the global database (Harris and Chapman 2001) to obtain an average reduced temperature profile (Fig. 4). The surface temperature record was then used as the forcing function, calculating the best fitting synthetic profile. This process requires determination of a baseline or POM temperature prior to the beginning of the surface temperature record (Chisholm and Chapman 1992; Harris 2007). The result, which combined the POM and the instrumental surface temperature record, indicated that there was approximately 1 °C of ground warming over the past 100–200 years (Harris and Chapman 2001), consistent with proxy methods of paleoclimate reconstruction (e.g., NRC 2006, and references therein) and comparable to other borehole analyses (Huang et al. 2000; Beltrami 2002b).

Summary

Temperature-depth profiles measured in boreholes are an important record of surface temperature change and can be summarized as follows:

1. Thermal diffusion in the solid Earth results in low pass filtering of temperature changes at the Earth's surface. Whereas annual mean temperatures are not resolved, the curvature in the temperature-depth profiles in boreholes reveals a surface temperature history at the site. The depth distribution of borehole temperature anomalies is related to the timing of surface temperature changes.
2. Both globally and regionally, ground temperatures show a predominantly warming signal consistent with surface temperature warming over the past two centuries.
3. Repeated temperature measurements in the same borehole can help improve the confidence in separating and interpreting steady-state and transient sources of curvature.
4. Geothermal climate change reconstruction techniques show approximately 1 °C of ground warming over the past one to two centuries, consistent with proxy methods of paleoclimate reconstruction.

Definition

GPS, Global Positioning System, is a US satellite-based navigation system which can accurately determine position, velocity, and time in a common reference system, anywhere on or near the Earth on a continuous basis.

Other Satellite-Based Navigation Systems

Next to GPS, several other global satellite-based navigation systems (GNSS) are in operation. Examples include Europe's Galileo (2009), Russia's Global'naya Navigatsionnaya Sputnikovaya Sistema (GLONASS, Russian Space Systems 2016), and China's BeiDou Navigation Satellite System (China Satellite Navigation Office 2019). Each of the systems emit a specific set of radio signals and all provide positioning, navigation, and timing capabilities following the same principles as described in the section “[Satellite Positioning](#).” We will here concentrate on GPS, but its principles can also be applied to the other GNSS or a combination of several GNSS. A detailed overview of GNSS is provided in Teunissen and Montenbruck (2017).

Satellite Positioning

Point Positioning

Satellite-based point positioning consists in determining the three-dimensional position (X, Y, Z) of a receiver, using the radio signals emitted by a number of satellites with known position. A receiver, usually located on the Earth, measures the travel time τ of the radio signal. Then it reconstructs the distance D between the receiver and the satellite by

multiplying the travel time τ by the velocity of the radio signals. In the ideal case, neglecting the influence of the Earth's atmosphere, radio signals travel with the speed of light c (299,792,458 m/s) and the distance reads $D = \tau \cdot c$.

Because the receiver and satellite clock are not perfectly synchronized, the measured travel time is corrupted by synchronization errors causing an error on the measured distance with respect to the true satellite-receiver distance. The unknown synchronization error dT between the satellite clock and the receiver clock then becomes the fourth unknown that the receiver has to determine, next to the three-dimensional (X, Y, Z) receiver position. Consequently, to solve this problem with four unknowns, at least four satellites have to be tracked simultaneously.

Relative Positioning

Differential or relative satellite positioning is a technique developed to improve the accuracy of satellite point positioning by combining the measured travel time at different receivers. The basic principle consists in reducing the biases at a “remote receiver” using measured biases at a fixed “reference receiver” with known coordinates. This allows removal of the errors common to the travel times measured at both stations. The position of the remote receiver (or the baseline vector) is then determined relative to the reference receiver. The corrections may be used in real time or later, using post-processing techniques. The remote receiver can be stationary or moving.

System Description

Introduction

Development work on the NAVSTAR/GPS (Navigation by Timing And Ranging/Global Positioning System) started in 1973, when the US Department of Defense (DoD) applied its technical resources to develop a highly accurate, space-based navigation system to replace the TRANSIT system.

The first GPS satellite was launched on February 22, 1978, and GPS Full Operational Capability (FOC) was declared in July 1995. FOC status means that the system meets all the requirements specified in a variety of formal performance and requirements documents. The system consists of three major segments: a space segment, satellites that transmit radio signals; a ground segment, ground-based equipment to monitor the satellites and update their signals; and a user segment, equipment which passively receives the satellite signals and converts satellites signals into position and navigation information.

Satellites, Signals, and System Time

The GPS is designed as a constellation of 24 satellites distributed among 6 orbital planes of which the inclination

with respect to the equator is 55° . The orbital planes have a radius of 26,600 km. Each satellite makes two complete orbits each sidereal day. With this constellation, one can always see minimum four satellites from any point on the Earth. In the original GPS design, the satellite signal consists of:

- The L1 and L2 carrier waves, with a respective wavelength of 19 and 24 cm.
- Information, encoded in the form of bits on the carrier signals by a process known as phase modulation:
 - The Coarse/Acquisition code or C/A, which is freely available to the public, is a binary code sequence which repeats every 1 ms. It is transmitted on the L1 carrier at 1.023 Mbps (million bits per second) using a binary-phase shift keying (BPSK) modulation technique. The “chip length,” or physical distance between binary transitions (between digits +1 and −1), is 293 m. Each satellite has a different C/A code, so that it can be uniquely identified.

The Precision code or P-code is transmitted on both the L1 and L2 frequencies at 10.23 Mbps with a chip length of 29.3 m and using the same BPSK modulation technique. The P-code repeats every 7 days, and like for the C/A-code, each satellite has a unique P-code. Whereas C/A is a coarser code appropriate for initially locking onto the signal, the P-code is designed for more precise positioning. Though the P-code is not classified, since January 31, 1994, a process called “anti-spoofing” encrypts the P-code in order to prevent an enemy imitating the GPS signal. To that end, the P-code was modulated with the W-code, a special encryption sequence, to generate the Y-code.

- The navigation message is modulated at 50 bit/s on the L1 wave on top of both ranging codes. It is sent in blocks of 1500 bits (taking 30 s to transmit). One message block is subdivided in three parts or five subframes. The first part, or first subframe, contains GPS date and time, plus the satellite’s status and an indication of its health. The second part, consisting of the second and third subframe, contains orbit parameters (often called the “broadcast ephemeris”) and allows the receiver to calculate the position of the satellite in the earth-fixed WGS 84 system defined in IS-GPS-200J (2018). The last part, consisting of the fourth and fifth subframes, is partly for military use but also contain information on the ionosphere (8 coefficients of the Klobuchar model, see Klobuchar (1986)), UTC data (Universal Time Coordinated), and the almanac data part. The almanac data contain information and status concerning all the satellites, their locations, and PRN (Pseudo Random Noise) numbers. The first and second

parts are identical in all transmitted 30-s blocks. The third part differs as it contains only 1/25 of the entire almanac. Hence, to receive the almanac of the entire constellation, a total of 25 blocks must be received, which takes 12.5 min.

The GPS signal is transmitted with enough power to ensure a minimum signal power level of -160 dBW at the Earth’s surface. The orientation of the satellites is always changing, such that the solar panels face the sun, and the antennas face the center of the Earth. For more details on the GPS signals and the navigation message, refer to the GPS Interface Specification (IS-GPS-200J 2018).

New demands on the existing GPS system pushed for a gradual modernization with newer generations of GPS satellites containing satellite signals not present in the original design. The GPS satellites in operation in 2019 are:

- Block IIR: launched after 1996, they have a lifetime of 10 years. They contain three rubidium atomic clocks.
- Block IIR-M: launched since 2005, these satellites transmit a second civil signal L2C on the L2 frequency and the military M signal on the L1 and L2 frequencies. The L2C signal aims at improving navigation accuracy, providing an easy to track signal, and acting as a redundant signal in case of localized interference. The satellites contain three rubidium atomic clocks.
- Block IIF: launched since 2010, the satellites emit a new L5 civil signal providing a second safety-of-life signal that meets the technical requirements for enabling aircraft to make precision landings in high multipath environments. The satellites carry four atomic clocks (cesium and rubidium).
- Block III: will carry a new L1C civil code, which will be transmitted on L1 in addition to current signals. This seeks to maximize interoperability with the Open Service signal of the European Galileo satellite navigation system. Further, Japan’s Quasi-Zenith Satellite System (QZSS) will transmit a signal with virtually the same design as L1C. A first Block III test satellite has been launched end of 2018.

GPS system time is a paper clock based on the atomic clocks in the GPS ground control stations and the GPS satellites themselves. The GPS Control Segment maintains GPS system time to within $1 \mu\text{s}$ of UTC(USNO) (IS-GPS-200J 2018) which is the realization of the UTC kept by the USNO (United States Naval Observatory, Washington, USA). However, GPS system time is continuous and does not follow the UTC leap-seconds. UTC(USNO) itself is kept very close to the international benchmark UTC as maintained by the Bureau International des Poids et Mesures in Paris.

GPS Ground Instrumentation

High-end GPS ground instrumentation generally consists of an antenna with hemispherical radiation pattern, connected to a receiver through a coaxial cable. GPS devices for the consumer market generally use small integrated antennas, resulting in a single portable device. For fixed GPS stations, portability is not an issue, but performance in terms of accuracy is. Consequently for this application, better, but larger, antennas and more complex, but more power consuming, receivers are used. Only the high-end instrumentation relevant for scientific use is discussed in this entry.

Antenna

Most GPS antennas in consumer electronics solely receive the primary L1 frequency. As a second frequency, however, allows for, e.g., correction of ionospheric delays which was already intended in the original system design (Spilker 1978), antennas for high-precision positioning will receive on both L1 and L2. From 2010 onwards, such antennas typically also receive the L5 frequency. This frequency resides in a band that is legally accredited for aeronautical use and hence enables dual frequency positioning in the world of aviation. Typically, these high-precision antennas will be mounted on locations with clear sky view in order to be able to track as many satellites as possible. This implies that the cable connecting the antenna to the receiver, somewhere inside a building, will have a length of several meters. To compensate for the signal loss in this cable, most high-precision antennas have a built-in low-noise amplifier (LNA). In most cases, the LNA is fed by a DC voltage put on the antenna cable using a bias-T, either inside the receiver or added in between antenna and receiver as an additional component.

As the fields emitted by the satellites are Right-Hand Circularly Polarized (RHCP) (IS-GPS-200J 2018), any antenna capable of receiving this polarization is able to receive the GPS signals. These can be wire antennas, such as helix antennas or crossed dipoles (e.g., the Dorne Margolin antennas included by many manufacturers), or circular patches.

In many cases, choke rings are added to the antenna in order to suppress the reflections (also known as multipath). These choke rings are cavities with a depth of approximately a quarter of a wavelength. As a consequence, multipath waves, generally coming in at negative elevation angles, will partly enter the cavities. After reflecting in the cavities, they will cancel out with those multipath waves that did not enter the cavity, thanks to a difference in path length of half a wavelength. This working principle is illustrated in Fig. 1. The concept of choke rings was first introduced by Jet Propulsion Laboratory (Tranquilla et al. 1989).

As the choke ring is typically a narrow band design, its performance can never be perfect on all (L1, L2 and L5)

GPS, Data Acquisition, and Analysis, Fig. 1 Working principle of the choke ring ground plane

frequencies. Therefore, many design improvements such as dual depth choke rings were proposed. Another problem linked with the antenna being multiband is the considerable variation of the phase center, which is the physical point where the signal is received. Fortunately, this can be measured and compensated for through an appropriate calibration procedure (Cohen and Parkinson 1991).

Receiver

A generic GPS receiver consists of a radio frequency (RF) part that demodulates the messages transmitted by the GPS satellites, and a positioning part that, based on the information received from the RF part, determines the position of the user.

Most GPS receivers allow storage of some variables (such as position and speed), and status information (such as system errors), and observables (such as code and phase measurements) in log files for further processing, mostly on removable memory cards. In combination with battery feeding, this should allow for autonomous operation for several days.

The RF block in the receiver demodulates the radio signals. In contemporary receivers, the RF block is made up of three separate RF front ends or receiving chains, in order to demodulate the signals of all satellites in view on the three different frequencies L1, L2, and L5. These signals are received by a single antenna, meaning that the receiver essentially gets a signal from the antenna that is the sum of all satellite signals on all carrier frequencies. Separation in the frequency domain is achieved by mixing down with different local oscillator (LO) signals in the different RF front ends. In order to distinguish between the signals from different satellites on a certain carrier frequency, the receiver uses code division multiplexing (CDM) techniques (Braasch and Van Dierendonck 1999). First, the receiver duplicates the antenna signal on a certain frequency into several identical copies.

Each of the identical copies will be sent into a different channel of the receiver. In every single receiving channel, a signature from a different GPS satellite will be sought for and the navigation message and the propagation delay of this satellite will be extracted. For cost reasons, this duplication is performed after down conversion of the original signal to a lower intermediate frequency (IF) and digitalization with an analog-to-digital Converter (ADC). Indeed, a digital signal can easily be copied to feed the distinct channels. Contemporary receivers have about 400 such channels.

Using a trial and error procedure by varying Doppler shift, carrier phase, and PRN time delays, the following steps are performed in each of the channels. The first step consists in removing the carrier by a numerical (digital) mixing of the IF signal with an internally generated carrier. The remaining signal only contains the PRN code and data bits. This signal is correlated with the satellite-specific PRN code generated by the receiver for varying time delays. In Fig. 2, the correlation with the received signal as a function of the time shift of the internally generated PRN is shown. Once the correlation of the internally generated replica of the PRN and the received signal succeeds, the Doppler shift, carrier phase, and code time delay of a certain satellite signal is determined. The channel is then said to be locked on to that specific satellite. Else, another PRN is tried.

Obviously, the more stable the receiver internal clock (mostly a quartz crystal) is, the more accurately the Doppler shift, carrier phase, and code delay can be determined.

However, due to systematic errors, the timescale of the receiver's clock deviates from the GPS timescale. If the difference between both approaches 1 ms, the receiver's time is resynchronized to the GPS timescale, resulting in a time jump, but assuring time correspondence of measurements from different receivers. In addition, signal noise and noise in the channel control loops will cause minor errors in the determination of these variables. These errors, referred to as measurement noise, will limit the precision of the position determination.

Only the PRNs of the C/A code, sent on L1, are publicly known. The encrypted Y-code's PRNs cannot be generated by the civil GPS receivers. Consequently, the civil receivers cannot receive the messages that were encoded with the military CDM. However, as the Y-code is sent on both L1 and L2, techniques of cross-correlating the signals on both frequencies are used to still allow determination of difference in arrival time of the P-code at both frequencies (Woo 1999).

If the channel is locked to a satellite, the correlation between the received satellite and the internally generated PRN code sequence will be strong. Then, in order to decode the navigation message, the sign of this correlation is investigated. If the correlation is strongly positive, a 1 was sent by the satellite; if it is negative, a 0 was sent. This way, the bits sent by the satellite can be demodulated. The demodulated navigation message, together with the Doppler shift, carrier phase, and pseudo range of the channel are then passed to the positioning block that will combine all information from all

GPS, Data Acquisition, and Analysis, Fig. 2 Correlation with the received PRN as a function of time shift of the internally generated PRN

channels to determine the receiver's position. Besides using the information from the RF block, the positioning block of most contemporary receivers can also take into account signals from correction streams from neighboring GPS receivers (see section “Positioning Modes”) or inertia sensors.

Measurements

The basic principle of the GPS measurement is that the GPS receiver determines the time lapse for each satellite between the signal emission and the signal reception (see the section “Receiver” for more details). By multiplying this time difference with the signal travel speed, the distance between the GPS receiver and emitting antenna of each locked satellite can be reconstructed. As will be shown later, this measured distance does not correspond with the geometric distance separating the receiver and satellite and is therefore called “pseudo range.” As already outlined in the section “Receiver,” two main types of measurements can be done by the RF block of the GPS receiver:

- Range observations, based on the time shift of the internally generated PRN codes, also called “pseudo-range” measurements.
- Carrier phase observations, based on the phase shift in the numerical IF mixing step in each receiving channel. They are more precise than the pseudo-range type measurements but have a much higher degree of “ambiguity” than the code ranges.

Code Pseudo-range Model

The GPS code pseudo-range P_i^k measurement at receiver i to satellite k can be expressed according to the following simplified equation:

$$P_i^k = \rho_i^k + c \cdot (dt_i - dt_i^k) + I_i^k + T_i^k + \varepsilon_{P_i}^k \quad (1)$$

where ρ_i^k is the geometric range from receiver i to satellite k , dt_i and dt_i^k are, respectively, the receiver and satellite clock offsets from GPS system time, while I_i^k and T_i^k take respectively into account the effect of the ionosphere and troposphere on the signal. Finally, $\varepsilon_{P_i}^k$ stands for the measurement noise components, including multipath.

Using Pythagoras Theorem, we know that:

$$\rho_i^k = \sqrt{(x^k - x_i)^2 + (y^k - y_i)^2 + (z^k - z_i)^2} \quad (2)$$

with $\vec{x}_i = (x_i, y_i, z_i)$ and $\vec{x}^k = (x^k, y^k, z^k)$ respectively the receiver and satellite positions (at signal transmission time).

For positioning or navigation purposes, the user wishes to determine the receiver position $\vec{x}_i$. As Eq. 2 is a nonlinear

equation, it is linearized around the a priori receiver position $\vec{x}_{i0} = (x_{i0}, y_{i0}, z_{i0})$:

$$P_i^k(t_i) = \frac{(x_{i0} - x^k)}{\rho_{i0}^k} dx_i + \frac{(y_{i0} - y^k)}{\rho_{i0}^k} dy_i + \frac{(z_{i0} - z^k)}{\rho_{i0}^k} dz_i + c \cdot (dt_i - dt_i^k) + I_i^k + T_i^k + \varepsilon_{P_i}^k \quad (3)$$

where (dx_i, dy_i, dz_i) denotes the deviation of the unknown receiver position with respect to its a priori value and ρ_{i0}^k the geometric range from receiver i to satellite k computed using the a priori receiver position.

For most applications, the satellite position $\vec{x}^k$ and clock synchronization error dt_i^k can be considered as known. This leaves the following unknowns (dx_i, dy_i, dz_i, dt_i) in Eq. 3. As previously mentioned, a minimum of four GPS satellites has to be observed simultaneously to solve for these four unknowns.

Carrier Phase Model

The GPS carrier phase Φ_i^k measured at receiver i to satellite k can be modelled according to the following simplified equation (expressed in [m]):

$$\Phi_i^k = \rho_i^k + c \cdot (dt_i - dt_i^k) + \lambda N_i^k - I_i^k + T_i^k + \varepsilon_{\Phi_i}^k \quad (4)$$

This equation differs from the pseudo range (Eq. 1) as follows:

N_i^k the initial cycle ambiguity: an integer associated with the first measurement (fractional phase) of a satellite track (or after a tracking interruption). After the initial measurement (and as long as there is no tracking interruption), the receiver keeps track of the cumulative phase differences reflecting the changes in distance to the satellite.

λ the wavelength of the carrier wave (L1, L2, L5 or any of their linear combinations).

$\varepsilon_{\Phi_i}^k$ the measurement noise of the phase observable, including phase multipath.

But this equation can be linearized in exactly the same way as the code pseudo-range equation (Eq. 1).

Remarks

The following comments can be made with regard to Eqs. 1 and 4:

- These equations are generic and several of the terms in the equations differ depending on the observed code pseudo-range (C/A, P1, or P2) or carrier phase (L1, L2, or L5) signal.
- High-end GPS receivers are programmed to measure GPS satellites simultaneously at the epoch t_i (e.g., at the full

second). Even if the reception times are identical, respective signals leave the satellites at slightly different times because the satellite-receiver distances differ. The signal transmission time t_i^k corresponding to the reception time becomes thus receiver-dependent (hence the use of the double index). The receiver clock error is identical in all simultaneous measurements at receiver i from all satellites. Using simultaneous code pseudo-range measurements to at least four satellites, the absolute position of the receiver can be computed rather straightforward. This is not possible when using carrier phases as the initial cycle ambiguity is an additional satellite-receiver-dependent unknown which has to be dealt with.

- Note the different sign for the ionospheric effect in Eqs. 1 and 4. The ionosphere, being a dispersive medium, acts differently on the group velocity (code) than the phase velocity and is consequently delaying the code measurements while it advances the phases.

Single and Double Differences

For relative positioning between two stations (i, j) , the observations made simultaneously to the same satellite k are differenced:

$$\Delta P_{ij}^k \triangleq P_i^k - P_j^k = \Delta \rho_{ij}^k + c \cdot \Delta t_{ij} + \Delta I_{ij}^k + \Delta T_{ij}^k + \Delta \epsilon_{Pij}^k \quad (5)$$

$$\begin{aligned} \Delta \Phi_{ij}^k \triangleq \Phi_i^k - \Phi_j^k &= \Delta \rho_{ij}^k + c \cdot \Delta t_{ij} - \Delta I_{ij}^k + \Delta T_{ij}^k + \lambda \Delta N_{ij}^k \\ &+ \Delta \epsilon_{\Phi ij}^k \end{aligned} \quad (6)$$

$\Delta(\cdot)_{ij}^k$ denotes the single difference. Note that the satellite clock difference errors are eliminated from Eqs. 5 and 6. If in addition, the difference between the single differences to two satellites k and l is taken, then the so-called double differences are constructed (indicated with $\Delta(\cdot)_{ij}^{kl}$):

$$\Delta P_{ij}^{kl} \triangleq \Delta P_{ij}^k - \Delta P_{ij}^l = \Delta \rho_{ij}^{kl} + \Delta I_{ij}^{kl} + \Delta T_{ij}^{kl} + \Delta \epsilon_{Pij}^{kl} \quad (7)$$

$$\begin{aligned} \Delta \Phi_{ij}^{kl} \triangleq \Delta \Phi_{ij}^k - \Delta \Phi_{ij}^l &= \Delta \rho_{ij}^{kl} - \Delta I_{ij}^{kl} + \Delta T_{ij}^{kl} + \lambda \Delta N_{ij}^{kl} \\ &+ \Delta \epsilon_{\Phi ij}^{kl} \end{aligned} \quad (8)$$

where the receiver clock difference errors, which are the same for both single differences, are also eliminated.

Although the use of single and double differences has many advantages (see section “Errors and Biases”), the differencing process increases the measurement noise level by $\sqrt{2}$ for each difference and introduces correlations between the differenced equations.

The double difference integer ambiguity ΔN_{ij}^{kl} in Eq. 8 plays an important role in accurate positioning using carrier

phase double differences. When the ambiguity is estimated together with the other parameters as a real number, a so-called “float solution” is obtained. If the estimated ambiguities can, however, be successfully constrained to their integer value, then an “ambiguity fixed solution” is obtained. This process of estimating ambiguity parameters, and then selecting the likeliest integer values, is known as “ambiguity resolution.” Once the L1, L2, or L5 ambiguities are resolved, and can thus be removed from the Eq. 8, the double-differenced phase observations become precise pseudo-range observations.

Errors and Biases

Introduction

GPS measurements are corrupted by biases (measurement errors that cause true ranges to be different from measured ranges by a “systematic amount”) and errors (internal instrument noise or residual biases) which limit the positioning accuracy. Three groups of GPS errors and biases are generally distinguished: receiver-dependent, satellite-dependent, and signal propagation errors.

Receiver-Dependent Errors

Measurement Noise

The measurement noise is included in the terms $\epsilon_{P_i}^k$ and $\epsilon_{\Phi_i}^k$ within the code pseudo-range (Eq. 1) and carrier phase (Eq. 4) measurements. Without biases contaminating the measurements, low measurement noise is expected to result in high accuracy positioning. The “rule-of-thumb” states that the measurement noise is at the level of 1%, or better of the wavelength (or chip length) of the signal. In the case of code pseudo ranges, this results in a measurement noise of 3 m for the C/A code and 0.3 m for the P-code. With their shorter wavelength, carrier phase measurements are less noisy implying millimeter noise for carrier phase measurements.

Receiver Clock Errors

GPS receivers are equipped with relatively inexpensive quartz crystal oscillators. The receiver clock error dt_i contaminates all satellite-receiver ranges. As mentioned in the section “Code Pseudo-range Model,” the solution to this problem is to treat the clock error as an additional parameter in the code pseudo-range estimation procedure. This allows estimating the receiver clock error with a precision of 10^{-8} to 10^{-7} s which is in addition satisfactory to access the exact measurement epoch of both code and phase measurements. An alternative strategy uses single or double differences (see Eqs. 5, 6, 7 and 8) to eliminate the receiver clock errors dt_i .

Antenna-Specific Errors

The precise point whose position is measured by a GPS receiver is the electrical phase center of the GPS receiver's antenna which is not the physical center of the antenna. The phase center will change with the changing direction of the signal from a satellite. The a priori receiver position $\vec{x}_{i0}$ has to be corrected for this effect. This behavior is different for each antenna at each carrier frequency and modelling it requires precise antenna calibrations (Görres et al. 2006). GPS antenna calibrations consist of two parts: (1) an average phase center offset with respect to a physical feature of the antenna and (2) the phase center variation (PCV) with respect to the satellite elevation angle and azimuth. Ignoring these phase center variations can lead to serious (up to 10 cm) vertical positioning errors. Even if the antenna calibrations have submillimeter accuracy, the access to absolute high-precision positioning is still limited by site-specific near-field multipath errors which can introduce systematic biases up to 1–2 cm, mostly in the estimated height component.

Multipath effects, included in terms ϵ_{pi}^k and ϵ_{di}^k in respectively Eqs. 1 and 4, are propagation errors arising from the interference of the direct signal by reflected signals from water or metallic surfaces or nearby buildings. The combined direct and reflected signals will give rise to incorrect pseudo-range and phase measurements. Low elevation signals are more susceptible to multipath effects than those at high elevations. The size of pseudo-range multipath error can reach 10–20 m on the C/A code (Evans 1986), while for the carrier phases, it can have a maximum value of a quarter of a cycle (4.8 cm for L1).

Using specific antenna design (see section “Ground Instrumentation”), careful antenna mounting, and advanced signal processing to filter out multipath integrated in the receiver can reduce the multipath errors. Using differenced code or phase observables will not remove the effect of multipath as the effect is receiver- and satellite-dependent. However, when using stationary receivers, an appropriate multipath mitigation can be implemented by taking advantage of the multipath time correlation due to the repeating satellite ground tracks (Wu and Hsieh 2010).

Cycle Slips

If the receiver loses lock on a satellite signal, due to, e.g., obstructions or interference, then the carrier phase observables might suffer from cycle slips. These cycle slips are jumps in the carrier phase measurements caused by the fact that when signal lock is reacquired, the integer initial cycle ambiguity N_i^k of the phase observable will be re-initialized. Cycle slips can occur independently on L1, L2, and L5.

The detection and repair of cycle slips is an important carrier phase data preprocessing step. Each time the software will detect a cycle slip, the cycle slip will be repaired (to restore the continuity of carrier cycle count) or a new

integer initial ambiguity N_i^k will be setup. If this is properly done, the cycle slips are not contributing to the error budget anymore.

Satellite-Dependent Biases

Orbit and Satellite Clock Errors

Computing the a priori geometric range ρ_{oi}^k (Eq. 3) implies known satellite position. The navigation message broadcast by the GPS satellites provides the user in real-time information on the satellite position and clock error. Following the International GNSS Service (<http://igs.org/>), the accuracy of the GPS broadcast orbits is at the 1-m level while the satellite clock error is given at the 5 ns level. The effect of the satellite orbit and clock errors (dr_i^k in Eqs. 4 and 6) propagates directly into the point position results and amplifies the positioning error.

In the case of relative positioning, the orbit errors dr (in m) propagate into errors db (in m) in the coordinates of a baseline of length b following the rule of thumb: $\frac{|db|}{b} = \frac{|dr|}{r}$ where r is the receiver-satellite distance (in km), typically 20,000 km. So, for a receiver inter-distance (or baseline length) of 100 km and an orbit error of 1 m, the error on the baseline components will be of the order of 0.5 cm. Following Beutler (1996), this rule of thumb is a bit too pessimistic and actually gives mainly an approximation for the propagation of the orbit errors on the estimated height component. For the horizontal component, the error can be divided by a factor of 3.

Precise GPS positioning (see ► “GPS, Tectonic Geodesy”) requires orbits with a higher precision than the ones provided in the broadcast navigation message. For that purpose, the International GNSS Service (IGS, see ► “Geodesy, Networks, and Reference Systems”) uses the tracking data from a worldwide GNSS network to generate the most precise satellite orbits and clocks related to the International Terrestrial Reference system (ITRS). Their accuracy typically varies between 2.5 and 5 cm for the orbits and ± 75 to 150 ps for the satellite clocks.

Antenna-Specific Errors

Each GPS satellite has a transmitting antenna which, like the receiver antenna, also has a phase center which changes with elevation angle and is influenced by the local environment around each satellite. The scientific community, mainly driven by the International GNSS Service, has made considerable efforts to accurately determine (or collect information about) the satellite's antenna phase center offsets and variations. The correct location of this phase center with respect to the satellite's center of mass is critical for accurate orbit determination.

Signal Propagation Biases

When travelling from the GPS satellites to the receiver on Earth, the radio signals cross and interact with the Earth's atmosphere. The two atmospheric layers that influence the

most the propagation of the GPS signals are the troposphere and the ionosphere. The atmospheric refraction has consequently an ionospheric, I_i^k , and tropospheric, T_i^k , component, each with their own spatial and temporal characteristics.

Ionospheric Refraction

The ionosphere is stretching from a height of about 50 km to more than 1000 km over the surface of the Earth; it is named so because it is ionized by the Sun's ultraviolet light. When the GPS signals propagate through this medium dispersion occurs, bending the signal and changing its velocity (Klobuchar 1991). The signal bending can be neglected for satellite elevations larger than 5° .

The ionospheric delay I_i^k is proportional to the number of free electrons along the GPS signal path, called the total electron content (TEC) which varies as a function of the latitude of the receiver, the season, the time of day, and solar activity (approximately 11-year cycle). At first order, the ionospheric delay on the carrier phases reads: $I_i^k = -\frac{1}{\cos z} \times \frac{40.3}{f^2} \text{TEC}$, with z the satellite's zenith distance. It ranges from about 50 m for signals at the zenith to as much as 150 m for low-elevation observations.

To reduce the ionospheric effect, a correction (using the Klobuchar model, Klobuchar (1986)) is transmitted within the GPS navigation message. However, it is generally conceded that the broadcast correction model corrects only 50–60% of the ionospheric delays, which is considered as the performance level of the model. For single frequency receivers, the use of the correction model parameters is often the only option for point positioning. Another source of information on the behavior of the ionosphere is provided by the IGS from their Global Ionospheric Maps (GIM) which consist of a global TEC grid ($2.5^\circ \text{ lon} \times 2.5^\circ \text{ lat}$) available at 2-hourly intervals. The IGS GIM maps have a typical accuracy of 2–8 TEC units.

In relative positioning, the ionospheric error will induce a baseline shortening dependent of the baseline length. For example, at a mid-latitude site using an elevation cutoff angle of 20° , a horizontal scale bias of -0.63 ppm is incurred for each $1 \times 10^{-7} \text{ m}^{-2}$ of TEC not accounted for.

As the ionosphere acts as a dispersive medium, the ionospheric delay is frequency dependent. Hence, if dual-frequency receivers are available, a special combination of the L1 and L2 signals, called the ionosphere-free combination L3, can eliminate the first order of the ionospheric effect. The ionosphere-free carrier phase measurement is:

$$\Phi_{L3} = \frac{f_1^2}{f_1^2 - f_2^2} \Phi_{L1} - \frac{f_2^2}{f_1^2 - f_2^2} \Phi_{L2} \quad (9)$$

with f_1 and f_2 , respectively, the frequencies of the L1 and L2 signals and Φ_{L1} and Φ_{L2} the carrier phase observables

(converted in m) on L1 and L2. A similar equation can be derived to construct the ionosphere-free code measurements. Using the ionosphere-free combination removes 99% of the ionospheric error. For applications requiring the highest positioning precision, the usage of ionosphere-free differenced observables is the most effective way of mitigating the ionospheric effect.

Tropospheric Refraction

The troposphere is the lower part of the Earth's atmosphere, and it is the seat of all meteorological phenomena (clouds, rain, hydrometeors, etc.). It contains approximately 75% of the atmosphere's mass and 99% of its water vapor and aerosols. The troposphere extends from the surface of the Earth to less than 9 km over the poles to 16 km over the equator. For radio frequencies below 15 GHz, it is a nondispersive medium meaning that it delays all GPS codes and carriers by the same amount so that the effect cannot be removed by combining observations made on two frequencies.

The tropospheric refraction delay T_i^k , depends on atmospheric pressure, temperature, and water vapor pressure. In addition, it is the shortest in the zenith direction (2 m) and increases when going down to the horizon (about 20–28 m for signals at an 5° elevation angle) as the air mass traversed by the signal increases (Brunner and Welsch 1993).

The tropospheric delay consists of a dry and wet component. The dry (or hydrostatic) component, which depends on surface pressure and represents about 90% of the delay, can be easily modelled. The most commonly used a priori model is the Saastamoinen model (1972), which is also recommended by the IERS conventions (2010). Today, the necessary pressure values input to the Saastamoinen model can be derived from numerical weather model data from the European Centre for Medium-Range Weather Forecasts (ECMWF).

The wet component of the tropospheric delay accounts for the remaining 10% of the delay and depends on the amount of water vapor along the signal path; it is much more difficult to accurately model.

Two kinds of troposphere biases can affect relative positioning: relative and absolute tropospheric biases. Relative troposphere biases are caused by errors of (mismodelled) tropospheric refraction at one endpoint of a baseline relative to the other endpoint, while absolute ones are caused by errors common to both endpoints of a baseline. Relative troposphere biases primarily bias station heights. For example, a relative troposphere bias of only 1 cm leads to an error of approximately 3 cm in the estimated relative station height for an elevation cutoff angle of 20° . This error increases to 19 cm for an elevation cutoff angle of 3° . Absolute troposphere biases produce scale biases of the estimated baseline lengths. For example, an absolute troposphere bias of 10 cm induces a scale bias of 0.05 ppm for an elevation cutoff angle of 20° and of 0.3 ppm for a cutoff angle of 3° .

For high-precision applications where mm accuracy is desired, the tropospheric bias at zenith is parameterized in the final position solution (see IERS Conventions 2010). For that purpose, different mapping functions (Niell 2000; Boehm et al. 2006) are used to express the dependency between the tropospheric delay at zenith and the one experienced at satellite's zenith distance. The Vienna Mapping Function (VMF1, Boehm et al. 2006) is recommended by the IERS for the applications requiring the highest accuracy. It is derived from data from the European Centre for Medium-Range Weather Forecast (ECMWF).

In addition, as with the ionospheric bias, the tropospheric bias is spatially correlated over distances up to several tens of kilometers meaning that differential positioning is an effective strategy for mitigating the effect of the tropospheric bias on positioning results.

Summary

As we have seen, all biases exceeding the measurement noise level have a high probability to degrade the accuracy of the positioning and should therefore be accounted for somehow. Various strategies have been developed to account for them:

- They can be estimated as explicit (additional) parameters, e.g., the receiver clock error and the tropospheric refraction.
- Common-mode biases can be eliminated or mitigated through combination of observables or datasets, e.g., by using of the ionosphere-free observable or relative positioning to mitigate the ionospheric and tropospheric refraction as well as satellite clock and orbit errors.
- The biases can be directly measured, e.g., antenna calibrations.
- The biases can be considered known or adequately modelled, e.g., by using precise satellite orbits and clocks from the IGS.
- They can be ignored, e.g., the phase multipath error at moving receivers.

Positioning Modes

Two main methods of positioning with GPS exist: point positioning and relative positioning. In addition, the precision of the obtained positions depends on the observables used: code and/or carrier phase data, the interval over which the data are accumulated before being analyzed, and the sophistication of the error modelling.

Point Positioning

GPS point positioning employs the data from a single GPS receiver.

Using code pseudo-ranges from at least four satellites, Eq. 1 can be used to compute the instantaneous receiver position and receiver clock error. With the broadcast ephemeris and ionospheric correction, a typical position accuracy of 22 m (2D rms) can be achieved using C/A codes. Typically, code pseudo-range positioning is used for low-accuracy real-time land, sea, and air navigation. The distinguishing characteristic of navigation is the urgency with which positioning information is required.

A more sophisticated method of performing point positioning uses the ionosphere-free combination of dual-frequency code and carrier phase observables. It is known as Precise Point Positioning (PPP) and allows reaching millimeter- to centimeter-level precision for 24-h solutions in static mode. To reach this precision, it is necessary to use the most precise satellite orbit and clock information (e.g., from the IGS) as well as a sophisticated error modelling. Up to a couple of years ago, PPP was only implemented in scientific GNSS analysis software. PPP has the advantage that it eliminates the need to acquire simultaneous tracking data from a reference station although it still requires external products delivered by global networks such as the IGS. Thanks to the IGS efforts to provide real-time orbit and clock information, PPP is becoming more popular (Bisnath and Gao 2008). Especially PPP with integer ambiguity resolution (PPP-AR, Shi and Gao 2013) can significantly improve the accuracy of PPP over short observation sessions, which is beneficial for fieldwork in many industries as it can potentially be used instead of the RTK positioning mode (see next section). PPP-AR is implemented by applying additional satellite corrections to mitigate unmodelled satellite equipment delays. These products are available from several agencies, e.g., Collins et al. (2014); Laurichesse et al. (2014). PPP-AR can also benefit from the availability of three frequencies (Geng and Bock 2013).

PPP has quickly become very popular for high-precision applications. Chen et al. (2018) showed, for example, how PPP using combined GPS and GLONASS measurements has become an effective method for monitoring crustal deformation caused by earthquakes.

Relative Positioning

Relative positioning employs two GPS receivers, a remote and a reference receiver, simultaneously tracking the same satellites (minimally four) to determine their relative coordinates (see section “Satellite Positioning”). It is based on the ability to eliminate, or significantly reduce, the common measurement biases across observations made simultaneously by GPS receivers see (Eqs. 5, 6, 7, and 8 and section “Errors and Biases”). Depending on the accuracy requirements, code pseudo-range as well as carrier phase

measurements can be used in relative GPS positioning. In addition, relative positioning can be implemented with different latencies varying from real time to post-processing:

- Carrier phase-based relative positioning

The basis of high-precision relative positioning is carrier phase measurements because of their low measurement noise. The problem of processing the “ambiguous” carrier phase data can be overcome by collecting sufficient epochs of data (up to 1 h or more) to ensure ambiguity resolution and strengthen the baseline solution. The reliability of the ambiguity resolution depends on:

- Baseline length
- The number of satellites (the more, the better)
- The satellite-receiver geometry
- Whether observations are made on both frequencies (it is much easier to resolve ambiguities when dual-frequency observations are available)
- The length of the observation session (the longer, the better)

Throughout time, GPS ambiguity resolution methods have become more and more sophisticated. The LAMBDA (Least-squares AMBiguity Decorrelation Adjustment method by Teunissen (1995)) allows now even on-the-fly ambiguity resolution using few observation epochs. This is typically necessary when the receiver is in motion. In addition, the availability of triple frequency signals open new possibilities for ambiguity resolution Cocard et al. (2008). An overview of different approaches is given in Li (2018).

At one extreme, static GPS surveying is the most precise positioning technique in use today. Observation times vary between 20 min to a day, depending on the expected precision, the distance between the two receivers, the number of visible satellites, and the satellite geometry. Measurements are typically taken at intervals between 10 and 30 s. After completing the field measurements, the data are processed on a PC using different processing options depending on, e.g., observation time and baseline length. For long baselines (>20 km), typically ionosphere-free carrier phases will be processed. For very long baselines (>1000 km), the user will process the data using high-precision scientific GNSS analysis software. In this case, mm to cm precision can be reached over distances exceeding 1000 km. Typical applications are the surveying of crustal or intraplate deformations (see ► “GPS, Tectonic Geodesy”).

At the other extreme, real-time-kinematic (RTK) GPS is the less precise relative GPS positioning method based on carrier phases. The main differences to static GPS surveying is the drastic reduction of the observation time and the fact that the position of the remote (or rover) receiver is often computed in real time. RTK can be carried out in real

time if an appropriate communications link (UHF radio modem, satellite link, cell phone, etc.) is provided over which the carrier phase data collected at the reference receiver can be made available to the remote receiver’s onboard computer. In this way, the remote receiver can generate the double differences, resolve the initial ambiguities, and perform the position calculations. Typically, measurements are taken at a 1 Hz rate and initial ambiguities are determined on-the-fly. In order to mitigate as much as possible the error sources, baselines should not exceed 10–15 km to reach the expected positioning precision of the order of 2–5 cm. Cadastre surveying is one of the applications that uses RTK. More information on RTK can be found in Langley (1998).

Other relative positioning modes based on GPS carrier phases are rapid static positioning and stop-and-go surveying. They are lying between the above-mentioned extremes.

- Code-based relative positioning is mostly known as real-time Differential GPS (DGPS). There are two ways to implement DGPS: (1) the fixed reference station broadcasts the differences between the measured pseudo ranges and actual (internally computed) pseudo range so that it can correct its pseudo ranges by the same amount before determining its position (method of range corrections); (2) the fixed reference station compares its known position with its computed position and sends the difference to the remote receiver which uses this difference to correct its computed position. The correction signal is broadcast using similar means as uses RTK. Range corrections are the preferred mode for real-time DGPS navigation. DGPS can deliver meter-level positioning that typically ranges between 0.5 and 5 m.

The standard format used to exchange GPS data in real time is RTCM 104 (cf. RTCM 2013). For the exchange of GPS data targeting post-processing, the RINEX (Receiver INdependent EXchange) format (IGS RINEX WG and RTCM-SC104, 2018) is used.

High-Precision Positioning

Static relative GPS surveying and PPP using ambiguity resolution both enable the most precise positioning. Millimeter-level precisions are obtained when GPS receivers are installed on a fixed location and the data are processed in post-processing ingesting a full day of GPS observations. This enables a wide variety of applications, such as the mitigation of the effects of vertical land motion in tide gauges (Santamaría-Gómez et al. 2012), the demonstration of correlations between water pumping and vertical ground deformations (Argus et al. 2017), the quantification of ground movements caused by the glacial isostatic adjustment

(Kreemer et al. 2018), or the study of volcanic processes (Fernández et al. 2017).

Conclusion

GPS positioning is based on measuring the travel times of radio signals emitted by satellites to a receiver mostly located on the ground. These travel times can be obtained by measuring on the precise, but ambiguous, GPS carrier phases or on the, less precise, GPS PRN codes. By multiplying the travel time by the speed of light, the distances receiver–satellites are reconstructed. Using minimally four satellites, the receiver can compute its position. Errors that influence GPS positioning are receiver-related (measurement noise, multipath, receiver clock errors, antenna phase center variation), satellite-related (satellite orbit and clock error, antenna phase center variation) or related to the signal propagation (ionospheric and tropospheric effect). As a lot of these errors are similar for GPS receivers distant of a few kilometers, relative GPS positioning was developed to improve the point positioning accuracy.

GPS is active since the mid-1980s. It has grown from a purely military navigation system to a scientific tool allowing today to measure deformations of the Earth's crust with millimeter-level precision. Today, GPS is mostly used together with other GNSS leading to even more robust and precise positioning.

Crustal deformation

Definition

Earthquake cycle A conceptual model that explains the buildup of stress that causes earthquakes, through a period of steady tectonic loading that culminates in sudden slip in an earthquake.

Slip deficit	The difference between the slip that has occurred over a period of time on a fault and the amount expected from the long-term fault slip rate; a measure of the accumulated slip “available” for an earthquake on the fault.
Displacement	The change in position of a point on the Earth’s surface.
Coseismic displacement	The final, static displacement of the surface caused by slip in an earthquake.
Postseismic displacement	Displacements caused by postseismic processes, which are transient deformation processes that follow large earthquakes.
Creep	Steady gradual fault slip that is aseismic (does not result in an earthquake).
Volcanic inflation	Dilatational deformation caused by pressurization of a volcanic system.
Glacial isostatic adjustment (GIA)	The deformation, mainly uplift, that results from the removal of glacial surface loads and the isostatic response of the crust and mantle.

Introduction

Tectonic geodesy uses measured displacements of points on Earth’s surface to study active tectonics. These motions mainly result from plate motions, slip on active faults (including earthquakes), and other earthquake cycle-related deformation, including transient fault slip. Additional deformation signals may result from the pressurization or depressurization of magma systems beneath volcanoes, hydrological deformation caused by aquifer and oil use, and changes in surface loads such as glacial isostatic adjustment (GIA), and these must be recognized and modeled so that they are not misinterpreted as tectonic signals. Geodesy is one of the most important tools for the study of plate boundary zones, the regions of distributed deformation that are commonly found at the boundaries of the major tectonic plates. The primary measurement tools today are GPS (now also including data from other global navigation satellite systems) and interferometric synthetic aperture radar (InSAR) (see ► [“GPS, Data Acquisition, and Analysis,”](#) and ► [“SAR Interferometry”](#)). Other geodetic techniques can provide similar data, but the spatial density and wide coverage of GPS and InSAR measurements are of critical importance.

Measurements of displacements depend on a precise time series of positions in a stable terrestrial reference system (see ► [“Geodesy, Networks, and Reference Systems”](#)). Usually, GPS time series are dominated by steady, linear motion over time, so site velocities are frequently used to describe site motions. However, as measurement capabilities have improved, we have found

more and more deviations from linearity in data from tectonically active regions due to fault creep events, post-seismic deformation, and non-tectonic sources like volcanic inflation and surface loading changes.

History of Tectonic Geodesy

Early work in tectonic geodesy dates back more than a century. The Dutch surveyor J. J. A. Müller reported ground movements associated with the 1892 Tapanuli earthquake in Sumatra, which caused changes in observed angles (Bonafede et al. 1992). H. F. Reid used displacements computed from geodetic surveys before and after the 1906 San Francisco earthquake as the basis for the elastic rebound hypothesis (Reid 1910, 1911). These observations supported the hypothesis proposed by G. K. Gilbert a few decades earlier that earthquakes were the result of a sudden release of strain that had built up over a long period of time (Gilbert 1884). Numerous studies over the succeeding decades used many kinds of geodetic measurements to document both sudden displacements due to earthquakes and the slow, steady deformation between them. By the 1970s, efforts were underway in the USA, Japan, and a few other countries to make extensive and systematic terrestrial geodetic measurements for the purpose of measuring crustal deformation. Although restricted in spatial coverage (usually to individual faults or fault systems), these data prompted the development of most of the conceptual and numerical models used in tectonic geodesy today.

Measurement of tectonic motions over large spatial scales began in the 1980s with NASA's Crustal Dynamics Project and related international efforts (e.g., the WEGENER project in Europe). This work started with a network of fixed (and a few mobile) very long baseline interferometry (VLBI) and satellite laser ranging (SLR) stations (see ► [“Very Long Baseline Interferometry”](#)) and later added GPS measurements. Today, data from more than 10,000 GPS stations are available and used by researchers around the world (e.g., <http://geodesy.unr.edu/PlugNPlayPortal.php>). High-accuracy GPS satellite orbits are available from the International GNSS Service (IGS), and the stations that contribute to the IGS tracking network form a reference network that any researcher can use to determine station positions in the International Terrestrial Reference Frame (ITRF) (Altamimi et al. 2016, 2017). Modern studies in tectonic geodesy are based on motions derived from time series of site positions expressed in the ITRF, on regional to global scales. Global compilations of site velocities from GPS have been used to measure plate motions and to develop a global strain rate map (Kreemer et al. 2014) and global elastic block models (e.g., Graham et al. 2018).

Plate Motions

Plate tectonic theory holds that the lithosphere can be divided into a set of rigid plates moving relative to each other (Fig. 1), with tectonic strain concentrated at their boundaries and caused by their relative motions. The motion of a rigid plate on the surface of a sphere is a rotation about an axis passing through the geocenter, so that the motions of all points on that plate are described by a single angular velocity vector. The surface projection of this axis of rotation is called the pole of rotation or Euler pole. Models of plate motions thus consist of angular velocities of plates relative to some reference frame or angular velocities of relative plate motions. Outside of known regions of tectonic activity, the plate interiors are rigid to a level comparable to the measurement precision of GPS (Calais et al. 2006; Argus et al. 2010), once non-tectonic effects like GIA have been removed (e.g., Kreemer et al. 2018; Ding et al. 2019).

In the early history of tectonic geodesy, geodetic results were validated to models of geologically current plate motions, as those were more precise at the time and their level of accuracy was understood. Magnetic anomalies at spreading centers and transform fault azimuths record the rates and directions of past relative plate motions, and estimates of current plate motions are determined from these data (averaged over periods of up to a few million years). In the early 1990s, comparisons showed that geologic and geodetic plate motion models were very well correlated once the geologic rates had been rescaled to match a then-recent revision of the geomagnetic timescale (Robbins et al. 1993; DeMets et al. 1994). Today, geodetic estimates are more precise than the geologic estimates. The first global plate motion models based on GPS data alone were Argus and Heflin (1995) and Larson et al. (1997). Larson et al. (1997) found that the motion of the Nazca plate was significantly slower than predicted by the geologic models, a result later confirmed by Norabuena et al. (1998, 1999), who found that the rate of subduction of the Nazca plate beneath South America has declined steadily over the last 20 million years. The most recent work (DeMets et al. 2010; Argus et al. 2010) confirms that geologic and geodetic plate motion rates are very similar despite the different timescales (a few decades vs. 780,000 years), although the differences in plate motions are statistically significant. This implies that changes in plate motions of a few to several percent have occurred over the last three million years (Argus et al. 2010).

Geodetic motions are understood most easily in terms of geologic structures when the velocities of sites are expressed relative to one of the major plates. But plate boundaries are always zones of distributed deformation (Figs. 1 and 2), which can extend over hundreds or thousands of kilometers and involve many active structures, especially within the continental crust (Thatcher 2003, 2009). These may include

GPS, Tectonic Geodesy, Fig. 1 Velocities of geodetic sites can measure both rigid plate motion and plate boundary deformation. The two panels show views of roughly opposite sides of the planet. Velocities on plate interiors are from Altamimi et al. (2017), in the ITRF2014 reference frame. The colored regions in plate boundary zones show the second invariant of the strain rate tensor from the Global Strain Rate Model v2.1 of Kreemer et al. (2014), with hotter colors indicating regions of higher strain rate. The stars show the poles of rotation

(in ITRF) for the North American (NOAM), South American (SOAM), Eurasian (EURA), Nubian (NUBI), and Somalian (SOMA) plates, also derived from Altamimi et al. (2017). Other plate poles of rotation are located outside of the view of figure or in locations that would obscure other features shown in the figure. The plate rotation is counterclockwise about the pole, except for the Somalian plate where the pole for a clockwise rotation is shown. Major plate boundaries are shown in red, based on Bird (2003)

rigid blocks or microplates, which often can be identified directly from the data as low-strain regions (Fig. 1; also, Kreemer et al. 2014), such as the Tarim and South China in the broad and complex India–Eurasia boundary zone (Fig. 2). Plate boundary zone deformation in Asia and North America has received a great deal of study, and work on these plate boundary zones requires an integration of the concepts of plate tectonics with the earthquake cycle and interseismic deformation, along with other causes of deformation detailed later in this article.

Steady “Interseismic Deformation”

Time series of site positions are typically dominated by steady, quasi-linear motion in time, aside from periodic seasonal variations that are generally related to surface loading (especially in the vertical component). This is true for sites both in plate interiors and often within plate boundary zones. As a result, many models reduce these time series to a site velocity based on a linear fit. A linear velocity fit needs to take account of any discontinuities or known time-dependent variations in the time series, such as those due to earthquakes, postseismic deformation, equipment changes, and other effects, as discussed in later sections.

The steady, linear motion of the tectonic plates leads to the concept of an “earthquake cycle,” in which tectonic stresses increase linearly with time until the fault undergoes shear failure, at which point an earthquake occurs and the stored stresses are relieved by fault slip (e.g., Scholz 1990). The basic concept goes back to Reid’s elastic rebound hypothesis (Reid 1910), in which he proposed that all of the strain that accumulates around a fault before an earthquake is accommodated along the fault when it suddenly slips, so that the net result of one full cycle is a block-like offset along the fault, with no strain off of it – much like what would be observed by geologists (Fig. 3). Assuming that the Earth has a linear elastic rheology, then strain and deformation should occur at a constant linear rate between earthquakes. Elastic earthquake cycle models thus imply a long “interseismic” period of linear deformation with time, punctuated by offsets during large earthquakes. Although there is unambiguous observational evidence for transient postseismic deformation following earthquakes, the concept of “interseismic deformation” remains useful.

Numerical models for the interseismic period follow directly from the earthquake cycle model. Large earthquakes within continental crust rupture a limited range of depths, from at or near the surface to a lower depth limit of (commonly) 10–20 km. Below this, observations of exhumed

GPS, Tectonic Geodesy, Fig. 2 Velocities of sites in the India-Eurasia plate boundary zone, relative to the Eurasian plate. GPS velocities are from Gan et al. (2007), and faults (red lines) are from Taylor and Yin (2009). Rigid rotation of two microplates or small plates, Tarim and

South China, is clearly visible in the velocity field at this scale. Most of the motions shown here can be explained by a combination of rigid block motion, including a number of smaller blocks and elastic deformation that results from the shallow locked zones of block-bounding faults

deep fault zones show evidence for ductile shear, presumed to occur continuously with time (summarized in Scholz 1990). Interseismic models commonly express this two-layer rheology using elastic dislocation theory. In the widely used model of Savage and Burford (1970), the fault zone creeps continuously at the long-term fault slip rate (accruing no strain) except for the shallow part, which remains locked by friction except in earthquakes. This is represented numerically by an elastic dislocation plane that creeps steadily from a locking depth d to infinite depth, embedded in an elastic half-space, which models the entire Earth as an elastic body. Alternatively, the slip on the fault as a function of depth can be represented by a linear superposition of uniform slip at all depths and backward slip, or backslip, on the shallow part of the fault. The fault does not actually slip backward; the backslip is a mathematical construct, one component of the linear superposition, and in fact represents the *slip deficit*, the degree to which the slip on the shallow part of the fault is interseismically trailing behind the long-term average slip rate. In the simplest earthquake cycle model, the slip in an earthquake would exactly compensate the accumulated slip

deficit over the interval between earthquakes, but in reality this is true only in a long-term average sense. Nevertheless, stress accumulates proportional to the slip deficit rate in all cases. In the two-dimensional case of an infinitely long strike-slip fault, the equations describing the dislocation model are very simple, with the velocity of a site located a distance x from the fault $V = (s/\pi) \cdot \arctan(x/d)$, where s is the average slip rate and d is the locking depth (Fig. 3). This velocity is expressed in a frame in which the velocity is zero at the fault and reaches $\pm 1/2$ the long-term fault slip rate far from the fault on either side. When the locking depth is shallow, the interseismic strain is concentrated close to the fault, and when it is deep, the strain is distributed over a larger region.

This simple model has proven to be extremely successful in a wide variety of tectonic settings, and the same conceptual model has been applied to normal faulting and subduction zones (Savage 1983). Savage and Burford (1970) and Savage (1983) assumed that steady slip would result in block-like or plate-like motion with all offset occurring as slip on the fault and no displacement or strain occurring in the surrounding rock, but this is strictly true only for a simplified fault

GPS, Tectonic Geodesy,

Fig. 3 Velocities and coseismic displacements expected from a simple elastic earthquake cycle model. The fault in this model is an infinitely long strike-slip fault (left-lateral) with a slip rate of 30 mm/yr., which has an earthquake after 100 years with 3 meter slip. During the interseismic period, the fault is locked from the surface to 15 km depth and slipping steadily below that. The interseismic deformation pattern (*top panel*) is shown by the arrows and solid line, relative to the far field on the left side of the fault. Compared to the uniform block motion that would result if the fault slipped uniformly at all depths (dashed line), the elastic response of the Earth spreads the fault shear over a broad area. The coseismic displacement (*bottom panel*) is antisymmetric about the fault, with maximum displacement at the fault (each side moves by half the coseismic slip, in opposite directions). The sum of 100 year of interseismic deformation and the coseismic displacement is a uniform block motion, shown by the dotted line

geometry such as a single planar fault. In other cases, the displacements due to the forward slip need to be calculated and included in the superposition (e.g., Cross and Freymueller 2008; Kanda and Simons 2010, 2012). Kanda and Simons (2010) further proposed a finite-plate elastic dislocation model for subduction zones, a generalization of the Savage (1983) approach.

When the locking depth varies along strike, the pattern of strain will also vary along strike; in the extreme limit of a locking depth of zero, the fault creeps at the surface at its long-term slip rate. Observations show a wide range of fault locking depths, generally in agreement with depths of maximum earthquake slip or depths of seismicity. Locking depths sometimes vary abruptly in the along-strike direction, for example, along subduction zones (Wallace et al. 2004, 2007; Cross and Freymueller 2008; Freymueller et al. 2008; McCaffrey 2008; Chlieh et al. 2008; Loveless and Meade 2010; Moreno et al. 2011; Nocquet et al. 2014; Chlieh et al. 2014; Protti et al. 2013). The parts of the fault determined (from geodetic data) to be locked by friction and accumulating slip deficit generally correspond well to the rupture areas of past great earthquakes.

The elastic dislocation approach to modeling interseismic deformation has been extended to three dimensions using elastic block modeling (e.g., McCaffrey 2002; Meade and Hager 2005a; Loveless and Meade 2011). In this approach, which blends the Euler pole description of plate motions with an elastic interseismic model, the model domain is first divided into a set of rigid blocks or microplates separated by block boundaries that represent faults and accommodate all relative motion. The velocity at any point on the surface is then the sum of two components, the rotation of the block it lies upon (described by the block angular velocity), and the elastic deformation caused by the slip deficit on all faults in the model (computed using elastic dislocation theory). The elastic block model enforces self-consistency of block motions, fault slip rates, and elastic deformation, with the only estimated or assumed parameters being the block angular velocities and the fault locking depths. Common practice is to assume a single locking depth for all or most crustal faults, although slip deficit distributions can be estimated. The inverse problem is linear when only block angular velocities are estimated and nonlinear when the locking depth or slip deficit distribution is estimated as well.

The elastic block modeling approach has been successful in describing deformation worldwide and has been extended to include uniform strain within some blocks (McCaffrey 2002; Nyst and Thatcher 2004; Meade and Hager 2005a, 2005b; Reilinger et al. 2006; McCaffrey et al. 2007; Meade 2007; Loveless and Meade 2010, 2011; Elliott et al. 2010, 2013; Johnson 2013). Graham et al. (2018) recently published a global reference elastic block model, the first attempt to extend this plate tectonics-like approach to plate boundaries globally, and used this model to estimate the global and regional moment-rate accumulation budgets.

Despite the general success of this approach, there is no way to account for time-dependent deformation within an elastic block model, so it must be removed from the data first. There have been attempts to develop viscoelastic block models, in which the predicted deformation rates evolve with time throughout the earthquake cycle (Johnson et al. 2007; DeVries et al. 2016). A major challenge for such models is that they are sensitive to both the viscosity structure and the recent earthquake history over decades to centuries, and in many places, there is not enough known to fully constrain the unknown model parameters. However, in principle such models integrate interseismic, coseismic, and postseismic deformation into a single framework.

The block modeling approach provides geodetic estimates of fault slip rates, which are in most cases consistent with longer-term geologic estimates (Thatcher 2009; Meade et al. 2013; Zeng and Shen 2014). However, there are a number of exceptions, and these may result from errors in data, inadequacies in the assumed block geometry, fundamentally non-block-like behavior, and neglected effects from viscoelasticity. In Southern California, a region with a notably complex network of active faults, several studies have concluded that viscoelastic block models give results more consistent with observed geologic slip rates than do purely elastic models (Chuang and Johnson 2011; Johnson 2013; Tong et al. 2014). Meade et al. (2013) argued that a transient rheology such as a Burger's body was required, as a viscoelastic model with a linear (Newtonian) viscosity would not explain the common agreement of geologic and geodetic rate estimates. An alternative explanation is that there is significant distributed deformation outside of the major faults, so that blocks are internally straining (Johnson 2013; Zeng and Shen 2014). Models that incorporate internally deforming blocks have also been proposed for parts of the Tibetan Plateau and India-Eurasia collision zone (e.g., Chen et al. 2004; Loveless and Meade 2011).

A prominent example of a remaining unresolved discrepancy between geological and geodetic slip rates involves the Garlock fault and Eastern California shear zone in the Mojave Desert of California (see discussion in Zeng and Shen 2014). The Garlock fault is a left-lateral strike-slip fault that is in a conjugate orientation to the right-lateral San Andreas fault

and the faults of the Eastern California shear zone. The present geodetic slip rate estimated for the Garlock fault is lower than expected based on the recent geological slip rate (McGill et al. 2009), while the reverse is true for the adjacent Eastern California shear zone. Models that incorporate time-dependent postseismic deformation have smaller discrepancies than elastic models, but this alone does not resolve the discrepancy (Tong et al. 2014). Dolan et al. (2007) and Oskin et al. (2008) suggested that time-dependent behavior of ductile shear zones in the deep crust may result in time-dependent fault slip, which in this case might result in switching between two modes: elevated slip rate on the Eastern California shear zone with low slip on the Garlock fault (the present) and elevated slip on the Garlock fault with low slip on the Eastern California shear zone (much of the geologically recent past).

Transient Fault Movements

Faults exhibit a range of transient slip behavior, including both spontaneous and triggered creep events. Distinct creep events of various sizes have been identified on several faults within the San Andreas fault system in California (e.g., Gladwin et al. 1994; Bürgmann et al. 1997; Lienkaemper et al. 1997; Taira et al. 2014). In recent years, particular focus has been placed on slow slip events (SSE) on subduction thrusts, also called episodic tremor and slip (ETS) events because the slip is usually accompanied by the emission of seismic tremor (Rogers and Dragert 2003). These transient fault movements are further evidence that the steady, elastic earthquake cycle model is a significant simplification of reality: even between earthquakes, there can be small variations in deformation. Mavrommatis et al. (2015) identified a decadal-scale slip event that preceded the 2011 Tohoku earthquake in Japan, which they interpreted as resulting from increasing slip rate and updip migration of deep creep down-dip of the eventual earthquake rupture. Recent lab experiments have produced spontaneous slow slip events in natural geological materials, opening up the possibility of testing hypotheses for the nucleation and evolution of these events in the lab (Ikari 2019).

SSE and ETS events were first observed in Japan (Heki et al. 1997) and at the Cascadia subduction zone (Dragert et al. 2001) in North America. A large number of these events have now been identified worldwide, and in most cases, the slip events are accompanied by emission of seismic tremor (Schwartz and Rokosky 2007). These events come in a range of sizes, many with slip and area equivalent to magnitude 6–7.5 earthquakes. The upper size limit for such events is not clearly defined. SSEs of decadal length have been detected or inferred from geodetic or paleo-geodetic (coral) data (Tsang et al. 2015; Li et al. 2016), and Meade and Loveless (2009) noted that scaling relations suggest that

average slip velocity decreases with event duration, such that multi-decadal SSEs might have slip rates slower than plate motion rates, making them appear like a case of “partial locking.” Small tremor bursts are also observed, as are smaller slip events too small to detect with GPS (but observed on strainmeters or tiltmeters). These mostly aseismic slip events, including small bursts of tremor that do not have resolvable geodetic signals, appear to follow a self-similar (power law) scaling relation like that of regular earthquakes but with a different power law exponent (Ide et al. 2007). Most large events recognized in the decade after Ide et al. (2007) have been interpreted as being consistent with the proposed power law scaling. However, Frank et al. (2018) argued that the large SSE in Guerrero, Mexico, in 2006 is more accurately described as a cluster of transient events with some relocking of the interface between events, which would result in a different scaling exponent.

Studies of SSEs at the Hikurangi margin (North Island, New Zealand) have been particularly important in improving our understanding, as events with a wide range of depths and durations (McCaffrey et al. 2008; Wallace and Beavan 2010) have been observed using an excellent on-land geodetic network along with temporary offshore pressure gauges (Wallace et al. 2016; Yohler et al. 2019). The detailed time dependence of slip in these events has been determined, and in some cases, events have influenced the slip history of neighboring segments (Bartlow et al. 2014). The 2016 Kaikoura earthquake triggered slow slip along much of the Hikurangi margin, as much as 600 km away (Wallace et al. 2017, 2018).

Prior to the recognition of SSEs or ETS events, the typical assumption in tectonic geodesy was that all deviations from a linear trend represented noise in the data, except when there was a known cause of displacement such as an earthquake or postseismic deformation. Today, deviations from a linear trend are likely to be considered signal, although it remains uncertain how to reliably distinguish between transient tectonic signals and noise; a particular focus of current research is in the automatic detection of transient events. A variety of approaches are used to identify temporal variations in individual time series and to use the spatial coherence of deformation signals as part of the event identification or to reduce ambiguities in the detection process (e.g., Ji and Herring 2013; Riel et al. 2014). The identified transient signals at multiple stations can then be inverted for a source model. However, noise in geodetic time series can be spatially correlated as well, and the separation of small transient signals from noise remains an area of active research.

Coseismic Deformation

Coseismic displacements are the sudden displacements caused by earthquakes. In large earthquakes they can extend

a long distance from the fault due to the elastic response of the Earth (Fig. 3). The earliest observations in tectonic geodesy were of the angle changes between triangulation stations caused by coseismic displacements. Today, GPS and InSAR displacements provide precise and spatially dense measurements of coseismic displacements, allowing detailed models of the distribution of slip in earthquakes to be determined; it is now common to use data from hundreds of GPS sites and thousands of InSAR pixels even after downsampling. Very large earthquakes are followed by periods of postseismic deformation during which deformation is aseismic (except for aftershocks) but is perturbed from the pre-earthquake pattern (see next section). Removing pre- and post-earthquake deformation from the coseismic displacements was, and still is, a significant challenge. Even in the era of dense continuous networks, the problem of separating coseismic and postseismic deformation has been pushed down to shorter timescales, as postseismic deformation is observed to begin immediately after the earthquake rupture terminates (Melbourne et al. 2002; Savage and Langbein 2008).

One of the earliest important earthquakes in the GPS era was the 1992 Landers earthquake in southern California. This M_W 7.4 strike-slip earthquake ruptured multiple faults with a complex surface rupture pattern (Sieh et al. 1993) and caused displacements of five continuous GPS sites in the region, which were used to develop slip models for the earthquake (Bock et al. 1993; Blewitt et al. 1993). Later, a much more extensive set of displacements determined from repeated GPS surveys of many survey marks in the region provided almost 100 displacement vectors that were used to develop detailed models of the distribution of slip during the earthquake (e.g., Hudnut et al. 1994; Freymueller et al. 1994). Work on the Landers earthquake demonstrated that even a small number of geodetic displacements provide significant constraints on the total seismic moment of the earthquake and that an extensive displacement field could reveal important details of the slip distribution. This earthquake was also the first large event to be imaged using InSAR (Massonnet et al. 1993).

The problem of estimating the earthquake slip distribution from surface displacement data is similar to that of modeling interseismic deformation. As in the interseismic case, elastic dislocation theory provides the mathematical basis for predicting surface displacements given slip on a fault and the inverse problem of estimating slip given surface displacement. Many studies have used the simplest elastic model, a uniform elastic half-space, while others have included the effect of elastic layering and/or sphericity of the Earth. For the largest earthquakes, a model that treats the Earth as a layered elastic sphere is necessary (Banerjee et al. 2005). The detailed fault geometry must be estimated as part of the inverse problem if not known from other sources. What is most different about the coseismic slip problem is that spatial

variations in the slip always must be estimated, and because the displacements are generally much larger than in the interseismic case, the data can resolve spatial variations in slip to a greater extent.

The most common approach to estimating the slip distribution is to segment the fault plane or planes into a mesh of “subfaults” assumed to each have uniform slip and estimate those slip values. This is done in an inverse approach (in which each column of the matrix used is the predicted elastic displacements from slip on a subfault), subject to smoothing between subfaults or other regularization to make the problem invertible. The subfaults should in principle be smaller than the spatial resolution of the data, to avoid oversmoothing possible small-scale variations in slip by the artificial choice of where the subfault boundaries are. An alternate approach is to vary the subfault size spatially as a function of the data resolution, so that the model is smooth where the data are sparse but can be rough where data are dense (Pritchard et al. 2002; Barnhart and Lohman 2010). Earthquake slip inversions also commonly use nonlinear optimization techniques, from least squares with inequality constraints (to constrain the slip direction) to full nonlinear inversions that are required when the fault geometry must be estimated (e.g., Ragon et al. 2018).

Bayesian inversion approaches offer an alternative to regularization-based inversion, in which the objective is to estimate not the best-fitting value of each subfault’s slip but rather its probability density function (pdf), by iterating through the model space with a Monte Carlo approach (e.g., Fukuda and Johnson 2008; Minson et al. 2013; Bagnardi and Hooper 2018). The likelihoods and correlations of the parameter estimates can then be directly explored rather than assumed based on an ad hoc regularization. Different regularization approaches based on mathematical constructs, physical properties (e.g., stress drop), or assumptions (e.g., self-similarity of slip) also can be tested within this same framework (Fukuda and Johnson 2008, 2010; Amey et al. 2018).

Large earthquakes cause substantial displacements very far from the fault, up to 1000 km for the 2010 Maule, Chile, and 2011 Tohoku earthquakes and up to 4000 km away for the 2004 Sumatra-Andaman quake. These far-field displacements can bias velocity estimates if not accounted for and can cause distortions of the geodetic reference frame. Tregoning et al. (2013) showed that the large earthquakes of the twenty-first century produced cumulative global displacements >1 mm over almost the entire planet and that the global deformation from these events was large enough to bias site velocities globally at the >0.1 – 0.3 mm/yr. level, if not accounted for. Past realizations of the ITRF have not consistently accounted for even some ~ 10 -mm-level offsets, but the latest ITRF2014 includes the most comprehensive set of coseismic displacements to date, along with postseismic displacement models (Altamimi et al. 2016).

In recent years, there has been a dramatic increase in the use of kinematic (high-rate) GPS to measure the ground motions during earthquakes. Nikolaidis et al. (2001) first demonstrated that kinematic GPS could record displacements due to seismic waves, but they were limited by having only data recorded once every 30 seconds. Larson et al. (2003) measured the propagation of surface waves from the 2002 Denali fault earthquake using GPS data recorded at 1 Hz, which demonstrated the utility of kinematic GPS for “GPS Seismology.” GPS displacement records are much less precise than records from seismometers, but can record large displacements faithfully, are not subject to distortion in the presence of tilts, and do not need external information to resolve integration constants because they provide a displacement record directly. Miyazaki et al. (2004a) determined a time-dependent slip model for the 2003 Hokkaido Tokachi-Oki earthquake in Japan based entirely on kinematic GPS records. This model clearly showed that slip propagated downdip and to the northwest from the hypocenter and also revealed a secondary slip peak to the northeast, which might represent triggered slip. The spatial and temporal resolutions of slip models estimated from kinematic GPS data are comparable to models derived from near-field strong motion recordings and superior to models derived purely from teleseismic recordings (Ji et al. 2004).

Real-Time Coseismic Deformation

Kinematic GPS solutions are increasingly becoming real-time solutions as well, driven by potential applications such as earthquake early warning and tsunami warning (e.g., Ruhl et al. 2017). Given a real-time stream of positions from a geodetic network, earthquake source parameters can be estimated directly from the time series. In the classic formulation of Gutenberg (1945), earthquake magnitude is a function of the peak ground displacement and the distance between the earthquake source and observation point. This relationship has historically been the basis of local magnitude estimation using seismic networks, but the relationship applies to displacement records measured geodetically as well and up to the largest magnitudes yet observed (Crowell et al. 2013; Fang et al. 2014). Geodetic magnitude estimates made in this way can correctly determine the magnitude to within ± 0.1 (moment with $\sim \pm 10\%$), which is comparable to the best magnitude precision from seismology, and can be made much more rapidly for the largest earthquakes.

Great progress has been made in the last decade in the development of real-time source model estimation. This requires multiple steps, some of which may be provided by or aided by seismic networks: (1) event detection, (2) displacement estimation, and (3) model estimation. Ohta et al. (2012) demonstrated an end-to-end system for all three steps. In other systems, the event detection can be triggered by notification from a seismic earthquake early warning system, and developments then focus on the displacement estimation

and/or source model estimation (e.g., Crowell et al. 2012; Minson et al. 2014; Grapenthin et al. 2014). As of 2019, test operational systems have been developed to support early warning and rapid situational awareness, and they performed well during the 2019 Ridgecrest earthquake in California (Melgar et al., submitted manuscript).

Postseismic Deformation

Postseismic deformation is the general term used for any kind of post-earthquake deformation induced by the stress changes in the earthquake. Tectonic strain is accommodated both by earthquakes in the upper crust and concomitantly by gradual aseismic deformation processes elsewhere in the crust and upper mantle (e.g., ductile flow and creep). The stress changes caused by earthquake slip perturb these aseismic processes, resulting in a strain pattern at the surface that evolves in space and time as dictated by the rheology of the crust and upper mantle (Bürgmann and Dresen 2008). Therefore, given sufficiently good data, postseismic deformation provides an opportunity to study this rheology and with it the dynamics of tectonic deformation (whereas interseismic deformation allows only a kinematic description).

Postseismic deformation is thought to result from a superposition of three main physical mechanisms, which operate on different spatial and temporal scales: viscoelastic relaxation in the mantle and possibly lower crust, afterslip on the very shallow or deep parts of the fault zone, and poroelastic relaxation. Poroelastic relaxation – fluid flow-driven deformation that relieves pressure differences caused by the earthquake – is generally considered to be important only very close to the fault and near geometric complexities such as fault stepovers and bends where dilatational strains are large (and fluid flow changes will thus be most significant). Shallow afterslip is a frictional process, first observed after the 1966 Parkfield earthquakes (Smith and Wyss 1968) and observed after many subsequent earthquakes, including subduction zone events (Hsu et al. 2006; Kreemer et al. 2006). Depending on the rheology of deep fault zones, deep afterslip may be a frictional process, a ductile shear process, or some combination of the two. Deep afterslip generally occurs immediately down-dip of the coseismic rupture zone.

Postseismic deformation can be large and long-lasting, although there is great variation from earthquake to earthquake. Because it tends to occur deeper and often is more spatially distributed than coseismic deformation, postseismic displacements are usually significantly smaller than coseismic displacements close to the fault but can be comparable to them in the far field.

In the first few years after an earthquake, afterslip and viscoelastic relaxation can produce similar deformation pattern at the surface, especially in the horizontal components,

which can make them difficult to separate given limited data. As a result, controversy over postseismic deformation models can linger for years, even for well-studied earthquakes. Afterslip decays more rapidly with time than viscoelastic relaxation (e.g., Suito and Freymueller 2009), so after a long time viscoelastic relaxation can be expected to dominate the post-seismic signal. Empirical kinematic afterslip models can be estimated from data in the same way that coseismic slip models are estimated. Afterslip also can be simulated in dynamic models as creep that accommodates the coseismic stress changes as per an assumed physical creep rheology, such as rate and state friction, and these models can be combined with viscoelastic relaxation (e.g., Barbot et al. 2009; Johnson et al. 2009). Key decisions in this kind of modeling include which parts of the fault are allowed to experience stress-driven afterslip and the 3D elastic and/or viscosity structure. Stress-driven afterslip models can be compared with kinematic afterslip models to test and validate these decisions (e.g., Zhao et al. 2017; Wang and Fialko 2018). Another complication is that the appropriate rheological model varies from place to place, and parameters such as mantle viscosity are both heterogeneous and poorly constrained (Bürgmann and Dresen 2008). As a result of these factors, many postseismic studies still make assumptions that certain displacements result from only the effect of one mechanism or attempt to use the spatial or temporal character of the observed displacements to constrain the mechanisms separately.

The 2002 Denali fault earthquake provides a useful example. Ten continuous GPS sites were set up within a few weeks of the earthquake, and nearly 100 sites were surveyed repeatedly over the next several years, providing a rich data set in space and time (Fig. 4). Both the spatial and temporal variations in postseismic displacements require more than one mechanism to explain them. All sites show an initially rapid rate of deformation that decayed over time. In general, site velocities were ~20 times faster than the pre-earthquake rates in the first 1–2 years, remained several times higher at many sites for several years, and remain significantly different even 15 years after the earthquake. A combination of empirical relaxation functions can explain the temporal decay of the displacements quite well as long as the model fit to the time series has both a short relaxation component (characteristic decay time of ~months) and a long relaxation component (characteristic decay time of a few years).

Postseismic models for the 2002 Denali fault earthquake have called upon a variety of mechanisms to explain the deformation. Freed et al. (2006a) showed that no single mechanism could explain the observed displacements and proposed a model combining afterslip within the lithosphere (approximated as a narrow low viscosity shear zone) and viscoelastic relaxation in the asthenosphere. Freed et al. (2006b) analyzed the time dependence at far-field sites and

GPS, Tectonic Geodesy, Fig. 4 Postseismic displacements following the November 2002 Denali fault earthquake. (a, b) Displacements are shown for each 2-year interval during the time periods 2003.5–2009.5 (a, top panel) and 2009.5–2015.5 (b, middle panel), with the color of the vectors indicating the 2-year interval (not all sites have data for all

intervals). Error ellipses (95% confidence) are shown only for the first interval in each panel for clarity. The pre-earthquake motions have been subtracted from both figures, so the displacements represent the transient motion only. The 2002 surface rupture is shown in white outlined with red. (c, bottom panel) The time series of eastward motion of the site

concluded that a model with a nonlinear (power law) viscosity in the mantle, consistent with lab measurements of the rheology of olivine, explained these data better than a model with a linear Newtonian viscosity. Johnson et al. (2009) estimated a combined afterslip and viscoelastic model, using an assumed frictional model. However, none of these models have been very successful in predicting displacements into the future, beyond the time span of the data used to constrain them (Freymueller et al. 2009). These model shortcomings likely result from a combination of deficiencies in the estimated coseismic slip model, from a failure to separate the different mechanisms correctly or from additional processes not considered in the models, possibly including Denali earthquake-induced changes in the slip rates on the subduction interface in southern Alaska (Johnson et al. 2009).

Similar patterns of postseismic deformation have been observed in many other cases, but individual earthquakes have displayed a puzzling variety of postseismic responses. For some large subduction earthquakes, postseismic transients seem to have decayed away after only a few years, while in other cases, small transient signals have lingered for decades. After the 1995 M_w 8.1 Antofagasta (Chile) earthquake, there was significant afterslip but apparently little viscoelastic relaxation of the mantle, as postseismic deformation rates returned to pre-earthquake rates within a few years (Melbourne et al. 2002). The 2003 Hokkaido Tokachi-Oki earthquake caused afterslip downdip of the coseismic rupture, which also extended at depth for a significant lateral distance north of the rupture zone (Miyazaki et al. 2004b). In the 2006–2007 Kuril Island doublet, a subduction thrust earthquake followed by a similar-sized outer rise event, afterslip appears to have been limited to the first several months after the thrust earthquake (Steblov et al. 2008; Kogan et al. 2011). The cause of this wide range of behavior is not fully understood, but likely reflects heterogeneity in material properties. For the largest earthquakes, significant postseismic deformation clearly can last for decades (Wang 2007); postseismic deformation from the great 1960 Chile and 1964 Alaska earthquakes remains very large (rates of 1–2 centimeters per year) decades after those large events (e.g., Suito and Freymueller 2009; Wang et al. 2012).

The 2011 Tohoku earthquake is another key event, because of the unprecedented scope of observations of postseismic deformation (see Wang et al. 2018 for a more complete summary). The dense data sets available onshore and offshore, as well as from the Asian mainland, have allowed authors to develop detailed models of the 3D rheological structure,

including weak zones within the lithosphere of the Japanese islands, variations in the asthenospheric viscosity, the spatial extent of the mantle wedge, and other factors (e.g., Sun et al. 2014; Hu et al. 2016). However, even with an unprecedented data set, competing studies still disagree on a number of details, and continued work with additional years of data will be required to fully resolve the remaining conflicts.

Because of the long duration of transient postseismic deformation and the short length of precise geodetic measurements in most places, it is not clear whether postseismic transients decay away to a relatively steady background deformation rate or whether deformation rates are never truly steady in time. This question has important implications for the dynamics of Earth deformation. Decay to a steady background rate suggests that tectonic deformation in the mantle and lower crust is localized due to lateral variations in properties and/or nonlinear viscoelasticity. The long-term fault motion rate and background deformation rate would represent a balance between tectonic forces and the effective viscosity of the weak zone beneath the fault. On the other hand, a uniform linear viscoelastic mantle requires that shear in the mantle be broadly distributed rather than localized beneath faults. In this case, surface deformation would never be steady in time except when the earthquake recurrence time and mantle relaxation time are roughly equal, and transient deformation would always extend a great distance away from every active fault, even a long time after the last major earthquake (Savage and Prescott 1978). The apparently linear “interseismic” phase would be essentially an illusion caused by our short measurement history. However, our ability to measure steady rigid plate motions that are very close to long-term geological plate motion estimates argues in favor of some degree of localization of strain in the mantle beneath faults, as does the observation that interseismic motions are localized around faults like the North Anatolian Fault in Turkey regardless of the time since the last earthquake (Hearn et al. 2009). This is also supported by the frequent consistency of geologic estimates of fault slip rates and geodetic estimates based on simple linear models. However, this question is not yet settled and probably will remain a focus of research for some time.

Volcano Deformation

Unlike tectonic deformation, which results mainly from slip on faults (shear sources), volcanic deformation results mainly

GPS, Tectonic Geodesy, Fig. 4 (continued) JANL (shown with a white dot in panels **a** and **b**) relative to North America illustrates the nonlinear character of postseismic deformation. Although the time series

appears to be nearly linear several years after the earthquake, there is actually significant curvature of the time series over the entire time period

from volumetric or dilatational sources, such as the expansion or contraction of a dike or sill or other magma body. Injection of magma into the subsurface through intrusion, or removal of magma from the subsurface as it is erupted, causes subsurface pressure changes that result in deformation at the surface. Volcanic deformation commonly results in horizontal displacements that are oriented radially away from or toward the volcano and includes significant subsidence or uplift (Fig. 5). Some volcanoes have produced very large deformation signals associated with the intrusion of magma before eruption, while others have produced only small deformation signals even as the result of large eruptions. The heterogeneity of behavior is a result in part of magma properties that vary with magma composition and gas content (e.g., compressibility). Generally, basaltic volcanoes like Kilauea, Okmok, and Etna (e.g., Neri et al. 2009; Aloisi et al. 2018) produce larger and more predictable surface deformation than more silicic volcanoes.

The simplest volcanic source model is a spherical point pressure source, usually called the Mogi model after the Japanese scientist who first applied it (Mogi 1958). This model describes the deformation at the surface caused by a pressure change in a small spherical body in an elastic half-space; the point source approximation actually holds even for relatively large bodies. The Mogi model provides a surprisingly good fit to observed displacements from many volcanic sources. Models for finite spherical or elliptical sources have also been developed; the finite spherical source is quite similar to the Mogi source except for very shallow sources, but elliptical sources produce a different pattern of displacements, still radial but with asymmetry in the amplitudes. Dikes and sills, planar bodies of magma that are associated with the opening and filling of planar cracks, can be modeled using the same dislocation theory that is used for shear faulting, using the equations for opening-mode deformation.

Volcanic deformation is inherently time-dependent, and volcanoes display episodes of both inflation (increasing pressure) and deflation (decreasing pressure). Noneruptive deflationary episodes probably result from a pressure drop caused by the leaking out of exsolved gases or from the depressurization of a hydrothermal system. During eruption, most volcanoes show deformation associated with decreasing pressure, although in a few cases there have been observations of simultaneous deflation at depth and inflation close to the surface. One example of this is the 2000 eruption of Usu volcano in Japan, for which deformation and gravity change data were fit best by a model with a deflation source at ~4 km depth, connected to the surface by an intruded fissure (Jousset et al. 2003). If the magma is assumed to be incompressible, such as for a magma that contains no exsolved gas bubbles, then the volume of magma added or removed to the subsurface is proportional to the pressure change in the reservoir or the opening or closing of a dike or sill, and thus the

deformation magnitude is proportional to magma volume. In general the magma will be compressible, and the deformation magnitude will be a function of the magma volume change, magma compressibility, and the elastic properties of the surrounding rock.

Recent modeling approaches attempt to better characterize the chemical and physical state of the magma and surrounding material. Some models attempt to incorporate geodetic, petrologic, and other data along with physics-based relations to describe rates of magma supply and how the magma changes before or during eruptions (e.g., Anderson and Segall 2011; Anderson and Poland 2016).

Unlike the tectonic problem, it seems that a simple “eruption cycle” model does not apply to volcanoes. The idea is appealing: magma would accumulate in the subsurface until the pressure reaches some critical level, which causes failure of the overlying rock, opening of a conduit to the surface, and then eruption. However, observations show that the magma supply is not uniform in time (Dvorak and Dzurisin 1993), while tectonic loading is, and successive eruptions at the same volcano can be quite different in volume and style. Even at volcanoes that erupt frequently, there does not appear to be a clear relationship between the volume of magma that accumulates between eruptions and the volume that erupts. This reflects the fact that the crust beneath active volcanoes may be occupied by a number of bodies of crystal mush or partially solidified magma and also the importance of gases and volatiles in triggering magma rise and eruption. A small intrusion of fresh, hot magma into a cooler body can trigger exsolution of dissolved volatiles and remobilization of the magma, causing a pressure increase that may be capable of triggering an eruption.

Okmok volcano in the Eastern Aleutian arc (USA) experienced substantial accumulation of new magma at shallow depth (Fig. 5) following its 1997 eruption, causing as much as several decimeters of displacement at the surface (Lu et al. 2005; Fournier et al. 2009), but its 2008 eruption was preceded by a period of ~3 years of relative quiescence. Albright et al. (2019) used a data assimilation approach with finite element modeling of the Okmok magma system to develop a hindcast of the eruption. This approach tracks not only the volume and pressure within the magma reservoir but also the stress state of the surrounding material. It successfully identified potential points of failure within the surrounding rock that could explain why the 2008 eruption created a new vent close to the magma reservoir rather than following the path of earlier eruptions.

Similarly, although rapid deformation at a volcano is an indication that the volcanic system is active, many episodes of deformation may occur between eruptions. Some large calderas, such as Campi Flegrei in Italy, Yellowstone and Long Valley in the USA, and Rabaul in Papua New Guinea, have experienced episodes of substantial inflation, deflation, or

GPS, Tectonic Geodesy, Fig. 5 Displacements from Okmok volcano, Eastern Aleutian arc, Alaska, showing significant volcanic deformation. The left panel shows displacements from 2001–2002, and the right panel from 2002–2003. The scale for vertical motion is different from that of the horizontal, and there is a factor of two difference in scale between the

two plots, a result of the much larger deformation in 2002–2003. The blue arrows are horizontal displacements, and the white bars show vertical displacements. Data are from Miyagi et al. (2004). The deformation results from the pressurization of a magma body located about 3 km below the surface

both over a period of many years (Dvorak and Mastrolorenzo 1991; Dvorak and Dzurisin 1997). Some of this deformation may result from pressure changes in hydrothermal systems associated with the volcano, rather than from changes in the magma reservoirs themselves. Other recent eruptions had only subtle or nonexistent deformation prior to the eruption, including the eruptions of St. Helens in 2004, Augustine in 2006, and Redoubt in 2009 in the USA (Cervelli et al. 2006, 2010; Lisowski et al. 2008; Grapenthin et al. 2013). However, significant precursory deformation very close to the eruptive vent certainly must happen. A notable example came from a continuous GPS site that was installed on Stromboli volcano (Italy), which showed dramatic displacements in the minutes before it was destroyed by an eruption from a new vent located at a very short distance away (Mattia et al. 2004). Such deformation, associated with the final rise of magma to the surface, is very localized.

Kilauea volcano in Hawaii showed distinctive and reliable patterns of deformation during its most recent 1983–2018 eruption, in which eruptive activity was centered at Pu‘u ‘O‘o on Kilauea’s middle East Rift Zone and from 2008 onward also at the Kilauea summit. Eruptions at Pu‘u ‘O‘o were preceded by inflation at the summit, which then deflated as a pulse of magma was intruded into the rift zone and proceeded downrift (Dvorak and Dzurisin 1993, 1997). Pressure changes and lava lake levels were closely coupled between the summit and at Pu‘u ‘O‘o, indicating an efficient hydraulic connection (Patrick et al. 2019). In April–May 2018, an M6.9 earthquake occurred and a dike was intruded

downrift into the lower East Rift Zone, beyond the extent of the 1983–2018 activity, and a new and voluminous eruption began out of a vent that formed within a residential neighborhood (Neal et al. 2018). This eruption substantially drained the summit reservoir, producing $\sim 0.8 \text{ km}^3$ of new lava from the vent and a collapse structure of similar volume at the summit.

Glacial Isostatic Adjustment and Sea Level Studies

The Earth also deforms in response to changes in surface loads, for example, changes in the mass of glaciers, ice fields, and ice sheets on the surface. The best-known example of this deformation is the dramatic uplift that has occurred in the regions formerly covered by the continental ice sheets in North America and Europe. The ongoing vertical motions in these regions, termed glacial isostatic adjustment (GIA), are dominantly driven by the viscoelastic response of the mantle to the unloading as the ice sheets collapsed after the Last Glacial Maximum (LGM), about 23,000 years ago. While the ice sheets were growing, the mass of the ice depressed the surface and induced stresses that caused the underlying mantle to flow out of the way. Upon collapse of the ice sheets, the process was reversed and mantle is still flowing back underneath at present. When the ice was in place, a flexural bulge formed in a ring around the glaciated area; now that forebulge is collapsing, producing subsidence across regions like the Eastern USA. In addition to the long-lasting effects of

the great ice sheets, deformation due to present-day ice mass changes can cause even more rapid deformation even though the ice mass changes are much smaller. Additional constraints on present-day ice mass changes come from in situ observations and airborne or satellite measurements of surface height change or gravity change.

Displacements from load changes are predominantly vertical. Horizontal displacements are usually several times smaller than the vertical displacements but are still significant relative to present geodetic measurement errors (e.g., Kreemer et al. 2018; Ding et al. 2019). Horizontal displacements are more sensitive than the vertical displacements to assumptions made in the computations (compressibility vs. incompressibility, radially symmetric Earth structure vs. lateral variations, etc.). Thus, while model predictions for the vertical motions are in general agreement, the best models for the horizontal motions remain a matter of considerable debate.

Conceptually, it can be useful to break up the deformation due to load changes into two components: an instantaneous elastic response and a time-delayed viscoelastic response (GIA). However, in areas with low mantle viscosities such as Iceland, Alaska, Patagonia, and West Antarctica, the viscoelastic response is so rapid that these two parts must be modeled together (e.g., Larsen et al. 2005; Auriac et al. 2013; Nield et al. 2014; Richter et al. 2016; Barletta et al. 2018). The theory for computing the elastic response of the Earth dates back to Love in the early twentieth century; Farrell (1972) used this theory to compute the response of a realistic Earth model to both point loads and disk loads. The viscoelastic problem results in time-dependent deformation, which can be computed in a variety of ways, either in terms of viscoelastic Love numbers or viscoelastic Green's functions for point or finite loads or using finite element methods.

Global models of deglaciation and GIA date back to the 1970s, with the development of models for the viscoelastic response of a 1D (radially stratified) spheroid and the development of the sea level equation to account for the gravitationally consistent redistribution of ocean water (e.g., Peltier and Andrews 1976; Clark et al. 1978). Models of post-LGM GIA were initially constrained by relative sea level histories, and more recently including geodetic data such as the gravity field and gravity change, and present-day displacement rates. Recent model developments and improvements include accounting for rotational feedback in the shape of Earth and changes in the paleo-shoreline position for improved description of loading on continental shelves. The most influential and commonly used models over the last few decades have been the series of ICE models from the University of Toronto (currently, ICE-6GD) and their corresponding mantle viscosity models (Peltier et al. 2015, 2018). However, the viscosity structure of the deep mantle remains a matter of considerable dispute, with different families of viscosity models having

values that can differ by an order of magnitude in the deep mantle (e.g., Lau et al. 2016). Increasingly, new studies are moving toward 3D mantle viscosity models rather than 1D radial models (e.g., van der Wal et al. 2015).

The BIFROST project in Scandinavia was initiated in the early 1990s to study GIA resulting from the post-LGM collapse of the Fennoscandian ice sheet and demonstrated the capability of GPS to measure accurate vertical motions (Johansson et al. 2002; Milne et al. 2004). The observations revealed the expected pattern of deformation, with the largest uplift rates (12–13 mm/yr.) located on the northwest margin of the Baltic Sea where the LGM ice sheet had its maximum thickness (Fig. 6). There have been fewer geodetic studies of GIA from the Laurentide ice sheet in North America (e.g., Sella et al. 2007). More extensive vertical motion data were included in the global ICE-6G model (Peltier et al. 2015) and the regional ICE-7G_NA model (Roy and Peltier 2017). The scale of the GIA deformation in North America poses an interesting problem: the estimates of horizontal motion relative to North America depend on the estimated motion of the North American plate in ITRF, but it is difficult to measure the motion of North America without having that estimate biased by horizontal GIA (Kreemer et al. 2018; Ding et al. 2019). As a result, independent estimates of the motion of the North American plate tend to differ by more than would be expected from data noise alone, and this has also made it difficult to evaluate the horizontal predictions of GIA models.

The most rapid uplift rates from GIA come from regions of present-day ice mass loss. Ice mass loss in Alaska and surrounding parts of Canada in North America and in Patagonia in South America has been very large since the end of the Little Ice Age (LIA) ~200 years ago, large enough to account for 10–20% of twentieth century global sea level rise (Dyurgerov and Meier 2005; Larsen et al. 2007; Lemke et al. 2007; Berthier et al. 2010). In both of these regions, measured uplift rates exceed 30 mm/yr. at their peak, and significant uplift has been observed in a broad area surrounding the regional ice fields. In Alaska, the observed uplift depends significantly on both the ongoing regional ice mass loss and the nineteenth century deglaciation of Glacier Bay (Larsen et al. 2005). Deglaciation rate is changing with time, generally accelerating but with considerable variation in response from glacier to glacier (Larsen et al. 2015; Hu and Freymueller 2019).

Mass loss in the Greenland and Antarctic ice sheets has begun or accelerated within the last decade, and the changes in mass loss rate are reflected in changes in the vertical motions. Southeast Greenland made the transition from no or minimal uplift to significant uplift in the early 2000s, while the onset of uplift in northwest Greenland began a few years later (Khan et al. 2008, 2010). The uplift history measured by GPS is in agreement with the mass loss history estimated by gravity observations of the GRACE satellite mission and is

GPS, Tectonic Geodesy, Fig. 6 Observations and model predictions for GIA in the Fennoscandian region, after Milne et al. (2001) using the BIFROST solution of Lidberg et al. (2007). (*left panel*) Horizontal velocities relative to the Eurasian plate (arrows, with 95% confidence ellipses) and vertical velocities (background color). (*right panel*) Model

predictions based on ICE-3G with lithosphere thickness 120 km, upper mantle viscosity $5e20$ Pa s, and lower mantle $8e21$ Pa s. This figure was provided by James L. Davis, Harvard-Smithsonian Center for Astrophysics

corroborated by direct observation and measurement of glacier mass balance in the area. The geographic focus of mass loss in the Greenland ice sheet has evolved over the last two decades, and while mass loss before 2010 was driven dominantly by the impact of ocean warming on tidewater glaciers, more recent mass loss has been increasingly driven by surface melting (Bevis et al. 2019). Measurements in Antarctica show extremely rapid rates of uplift in the Amundsen Sea Embayment (ASE) and Antarctic Peninsula (e.g., Nield et al. 2014; Barletta et al. 2018). Uplift rates across the rest of the continent (e.g., Sasgen et al. 2018) are substantially lower.

As glaciers, ice fields and ice sheets lose mass, most of the water ends up in the ocean where it raises sea level. Tide gauges measure relative sea level, which is the level of the ocean surface relative to the land surface. Estimates of twentieth century global sea level rise depend on averaging over a global set of tide gauges where uplift or subsidence of the land is negligible, but more data could be used to analyze sea level variations if land uplift rates at tide gauges were precisely known. Wöppelmann et al. (2009) used GPS measurements at a globally distributed set of tide gauges to correct for vertical motions of the land and estimated an average global sea level rise of 1.6 ± 0.2 mm/yr., assuming that the vertical motions observed by GPS over the last decade are representative of the last 100 years. This estimate agrees with previous estimates

for twentieth century sea level rise. However, their uncertainty estimate did not account for the uncertainty in the geocenter stability of the ITRF, which was actually the dominant error source. Wöppelmann and Marcos (2016) updated these results but pointed out that the accuracy of the terrestrial reference frame currently limits our ability to measure global average sea level using GPS to the ~ 0.5 mm/yr. level.

Sea level does not rise uniformly around the globe when there is a significant redistribution of mass resulting from the melting of ice. Spatial variations in sea level rise result from changes in the geoid caused by the mass redistribution; sea level follows the geoid, so if the geoid height is increasing over a section of ocean, then local sea level would rise in a geocentric reference frame (Mitrovia et al. 2001; Tamisiea et al. 2001). The difference between relative sea level variations measured by tide gauges and vertical motions measured by GPS is a combination of vertical motion of the land, sea level rise due to the addition of water to the oceans, ocean thermal expansion, and the local geoid change. Geoid rate changes at the multiple mm/yr. level are predicted for areas of significant regional mass loss, such as Alaska and Patagonia, and significant geoid height trends have been measured using GRACE (Tamisiea et al. 2001, 2005). Much larger variations in the geoid would appear in the future if the Greenland and Antarctic ice sheets melt significantly (Mitrovia et al. 2009).

Future studies will integrate data and models for all of these effects to provide a complete and self-consistent picture of sea level, gravity change, and height change around the world's coastlines.

Summary

High-precision geodesy is an important tool for the study of active tectonics and other causes of crustal deformation. Motion and deformation of points on the surface of the Earth result from a combination of tectonic plate motions, elastic deformation from the slip deficit associated with faults that are locked by friction, and coseismic and postseismic displacements. Additional causes of deformation in some places include pressure changes within volcanic systems and past and present surface load changes, most importantly from the melting of ice in glaciers, ice fields, and ice sheets. Deformation due to several sources may be superposed in some locations, such as southern Alaska and Patagonia. Surface displacements can be related to the underlying sources using elastic or viscoelastic deformation models, the most important of which are based on dislocation theory.

Gravimeters

Andrew Hugill
Scintrex Ltd, Concord, ON, Canada

Synonyms

Gravity meters; Relative

Definition

An instrument which measures differences in gravity. Units: Practical units are mGal (10^{-6} g) and μ Gal (10^{-9} g). 1 Gal = 1 cm/s^2 .

Introduction

The first relative gravity measurements were made in 1672 by the French astronomer, Richer, who noted a difference in the period of a pendulum when observed in Paris and close to the equator in Cayenne, South America. For the next two centuries, relative gravity measurements, mainly for scientific purposes, were made with pendulums. In 1893, Threlfall and Pollock made the first successful spring-mass gravimeter in Sydney, Australia (Threlfall and Pollock 1900) using the newly discovered quartz fibers. From the middle of the twentieth century up until the present nearly all relative gravity measurements have been made with instruments based on a mass suspended by a quartz or metal elastic system. Instruments in which the mass is levitated in the field of a

superconducting magnet and instruments based on inertial-grade accelerometers are also used in some applications.

Because they are not intrinsically calibrated, relative gravimetry rely on measurements made by absolute gravity meters (see the ► “Gravity Measurements, Absolute” entry of this encyclopedia) for calibration.

Relative gravimeters can be classified into three types according to the mode in which they are operated, with each mode of operation having different performance requirements:

1. Survey: Measurement of relative gravity as a function of position on, or under, the surface of the earth or on the sea floor
2. Stationary: Continuous measurement of changes in gravity or low-frequency earth motion as a function of time at a fixed location on, or under, the surface of the earth or on the sea floor
3. Dynamic: measurement of relative gravity as a function of position from a moving platform such as an aircraft or a ship

Performance Requirements

Basic performance requirements for relative gravimeters are listed in Table 1. These must be met under a range of environmental conditions according to the mode of operation. Dynamic instruments have to be able to produce data while moving and subject to relatively large accelerations, whereas the defining characteristic of survey instruments is the capability to withstand acceleration and shocks during transport without sustaining changes in the reading value.

Survey instruments can be subdivided into borehole, sea-floor, and land gravimeters all with the same basic performance requirements. However, borehole and sea-floor instruments must have remote reading capabilities and be packaged to withstand high pressure. In addition, borehole instruments have size restrictions and are required to operate at higher temperatures. Survey gravimeters have a useable sensitivity of less than 5 μGal (e.g., Zumberge et al. 2008; Merlet et al. 2008). A total range of 7000 mGal covers the gravity field on

the surface of the earth. A minimum continuous operating range of around 50 mGal is needed to provide useful measurement capability.

Stationary gravimeters can be divided into those which are located in an observatory and smaller, less cumbersome portable or transportable instruments (Crossley et al. 2013). Most applications for observatory instruments (Crossley et al. 1999) are in the frequency range from dc up to approximately 7 mHz which is the maximum frequency at which the seismic normal modes are resolvable (Ingate and Berger 2004). Minimum earth noise in this band is around $3 \times 10^{-2} \mu\text{Gal}/\sqrt{\text{Hz}}$ (Ingate and Berger 2004), which represents the minimum useful instrument sensitivity. Superconducting instruments and the metal spring instruments which approach this sensitivity (Banka and Crossley 1999) have a range of a few mGal or less and are saturated by surface waves of large earthquakes (e.g., Mansinha and Kamal 1992; Agnew et al. 1986). More recently, interest has turned from using stationary gravimeters for global studies to applications related to hazard monitoring and climate change (Crossley et al. 2013), including volcano, earthquake, and aquifer monitoring. Although, in some cases requiring the same levels of performance as observatory gravimeters, the instruments used in these studies need to be portable so that they can be moved to locations where the largest signals are found.

Useable sensitivity for airborne gravity meters is limited by GPS precision as described in the *Sensor motion and orientation* section below. With a 100 s low pass filter, this limit is around 0.5 mGal (Argyle et al. 2000).

Technology

Sensor Technology

Relative gravimeters are based on one of the four core technologies listed in the top row of Table 2. Technologies have characteristics which better suit them to particular types of gravity meter as discussed below.

Fused Quartz

Fused quartz sensors perform well in survey gravimeters because quartz has high strength, remains almost perfectly elastic up to its breaking stress, and can be welded into compact structures which have exceptional mechanical integrity. Sensors are free of tares when transported and do not have to be clamped between readings, making them accurate and quick and easy to operate. The relatively high long-term drift of quartz springs is linear enough to be compensated electronically for survey applications.

Metal

Metal spring-mass sensors have very low long-term drift and low temperature coefficient, making them well suited to

Gravimeters, Table 1 Gravimeter performance requirements

Type of gravimeter	Performance			
			Range (mGal)	
	Signal bandwidth	Sensitivity (μGal)	Total	Continuous (min)
Survey	Dc	1–10	7000	50
Stationary: Observatory	Dc – 10 mHz	$3 \times 10^{-2}/\sqrt{\text{Hz}}$	7000	2
Stationary: Portable	Dc – 10 mHz	1	7000	2
Dynamic	Dc – 10 mHz	500	10,000	10,000

Gravimeters, Table 2 Gravity sensor core technology

Technology Type of gravimeter	Spring/mass		Superconducting	Inertial-grade accelerometer
	Quartz	Metal		
Survey				
Stationary				
Dynamic				

stationary measurements. However, they are more susceptible to tares in response to transportation because the elastic properties of the materials in their elastic suspension are inferior to those of quartz. Also they are assembled from a number of components fixed together, so they do not have the integrity of a welded quartz structure. These inherent disadvantages have been overcome by clamping the mass during transportation and careful handling, but at the expense of added manufacturing complexity, requirement for more skillful operators and lower productivity in the field. Historically, survey gravimeters based on metal spring-mass sensors were used extensively in survey operations because of their low long-term drift and high accuracy, especially for establishing gravity networks and other applications which require measurement of gravity at widely separated points. Absolute gravimeters are now used to make large-scale network-type measurements and survey instruments with metal spring-mass sensors are being replaced for most other applications by modern quartz instruments which are easier to manufacture and operate, and make extensive use of electronics to obtain similar or better performance.

Metal spring-mass gravimeters were first used for dynamic applications in the late 1950s (Dehlinger 1978). Since then, they have been continually refined and modified for this application and are in widespread use (e.g., Williams and MacQueen 2001; NOAA Grav-D project 2017).

Superconducting

The superconducting gravity sensor is described by one of its inventors (Goodkind 1999) as “a spring type gravimeter in which the mechanical spring is replaced by a magnetic levitation of a superconducting sphere in the field of superconducting, persistent current coils.” Because these currents are very stable, the sensor has extremely low drift which makes it well suited for stationary operation.

Inertial-Grade Accelerometers

These are devices that have been developed for inertial navigation systems so have excellent dynamic performance on moving platforms and are very compact. They have sufficient sensitivity for dynamic operations, but not for survey or

stationary operations. An example of an inertial-grade accelerometer is the Q Flex QA3000 which has a volume of approximately 1 cu. inch and is built around a chemically machined quartz suspension (Foote and Grindeland 1992). Another example is the Bell Aerospace accelerometer (Torge 1989) which has similar dimensions.

Design Principles

A generalized signal flow diagram for relative gravimeters is shown in Fig. 1. The proof mass is suspended so that it moves in a well-defined trajectory in response to a change in the gravitational force on it. The proof mass and suspension are termed the gravity sensor. The gravity reading is derived from the input to the calibrated feedback actuator that returns the output of the displacement sensor to the reference value. Feedback force is applied to the proof mass through an electric field or electromagnetic actuator and/or through a change to the suspension geometry.

Gravity Sensor Natural Period, Sensitivity, and Seismic Noise

The design principles of the gravity sensor determine important performance characteristics of the gravimeter that are largely independent of the technology used in construction.

The gravitational force on the mass of a spring-mass gravity sensor is balanced by the elastic force generated by the extension of a quartz or metal spring. The extended length of the spring is given by $l = \frac{mg}{k} + l_u$ where k is the spring constant and l_u is the unstressed length of the spring. A change in gravity from a value g_0 to $(g_0 + \Delta g)$ produces a change in spring length from l_0 to $(l_0 + \Delta l)$ where $\Delta l / (l_0 - l_u) = \Delta g / g_0$. As Δl is proportional to $(l_0 - l_u)$, this simple spring-mass system is termed a proportional sensor, or to use the language of seismometry, a short-period sensor.

For a practical sensor with $l_0 - l_u = 2$ cm and a change in gravity of 0.01 mGal ($1 \text{ Gal} = 1 \text{ cm/s}^2$), $\Delta g / g_0 = 10^{-8}$ and the displacement which must be detected is $\Delta l = 2 \times 10^{-10}$ m. This system responds equally to gravity and acceleration up to its natural frequency $f_n = \frac{1}{2\pi} \sqrt{\frac{k}{m}} = \frac{1}{2\pi} \sqrt{\frac{g_0}{(l_0 - l_u)}} = 3.5 \text{ Hz}$, so

Gravimeters, Fig. 1 Relative gravimeter functional diagram

unwanted signals, including microseismic and cultural noise, would need to be filtered from the output to recover the gravity signal.

It was not until the 1970s and 1980s that electronics were available to detect sub-nm displacements and effectively filter signals in a portable instrument. The Scintrex CG-3 gravity meter, introduced in 1987, and its successors the CG-5 and CG-6 are based on a proportional spring-mass system and use capacitive displacement sensing and digital filtering to achieve the required level of sensitivity and noise reduction (Hugill 1990).

Before the advent of modern electronics, many mechanical design concepts were developed (e.g., Hugill 1984) to increase sensitivity and reduce natural frequency, and thus noise response, of sensors enabling detection of gravity-induced mass displacement by eye, through a microscope. Sensors with increased mechanical sensitivity are termed “astatic” and are analogous to long-period seismometers. The most successful of these was the LaCoste suspension based on a “zero-length spring” with an unstressed length l $u = 0$ (LaCoste 1934). Worden-type and LaCoste and Romberg gravimeters, which were introduced in the 1940s and 1950s, are based on the LaCoste suspension.

The sensor in the superconducting gravimeter (Goodkind 1999) is also astaticized with its sensitivity being increased by adjusting the relative current settings in two collinear coils to shape the magnetic field gradient in the vicinity of the levitated proof mass.

Displacement Sensing and Feedback

Most modern gravimeters use capacitive displacement sensing and either electromagnetic or electrostatic feedback. Electrostatic feedback allows sensor design to be simplified as the same electrodes can be employed for sensing, using high frequency excitation, and feedback at lower frequencies

(e.g., Block and Moore 1966; Hugill 1984). Examples of instruments using capacitive displacement sensing and electrostatic feedback include the Scintrex CG-3, CG-5 and CG-6 (Hugill 1990) and the micro-g LaCoste gPhone (Micro-g LaCoste 2019).

Electromagnetic feedback has the advantage of inherent linearity and a higher force capability. Instruments with capacitive displacement sensing and electromagnetic feedback include the Bodenseewerke GSS30 (Torge 1989), the superconducting gravimeter (Goodkind 1999) and inertial-grade accelerometers. In the latter, feedback supports the full gravitational force on the mass so the spring suspension only provides constraint of the proof mass motion (e.g., Foote and Grindeland 1992), which is equivalent to having no zero offset in Fig. 1.

In most gravimeters with the LaCoste suspension, the top of the mainspring is moved to null the mass. This is done in Worden-type meters through a gearbox, screw thread, and auxiliary springs. In the LaCoste and Romberg g meter (LaCoste and Romberg 1945), the top of the spring is connected to a lever system which is moved by the operator through a calibrated gearbox and screw thread. The required displacement of the top of the spring to null a change in gravity of 0.01 mGal is 0.25 nm (Torge 1989). Electrostatic feedback systems are installed in gravimeters with metal LaCoste suspensions as an option for survey instruments to make reading easier and more accurate (e.g., Webring et al. 2004; ZLS 2019) and to enable high-sensitivity automatic reading for stationary instruments (e.g., Block and Moore 1966).

Error Sources

Error sources can be divided into three broad groups: those generated by the gravimeter or intrinsic error sources, those

resulting from the response of the instrument to external inputs, and those resulting from the effects of transportation.

Intrinsic Error Sources

Scale Factor Changes

Changes in the scale factor of gravimeters with quartz sensors can be as high as 10^{-3} in the first year after manufacture; subsequent changes are of the order of 10^{-4} – 10^{-5} per year (Zumbege et al. 2008; Meurers 2018; Carbone and Rymer 1999). Changes of around 10^{-3} have also been reported in metal spring sensors (Carbone and Rymer 1999). In contrast to the smooth drift in the scale factor of quartz sensors, the reported changes in the metal spring sensor were abrupt and separated by long periods of stability.

As the scale factor, k , relates a reading differences ($R_2 - R_1$) to the gravity change ($g_2 - g_1$) through the expression ($g_2 - g_1 = k(R_2 - R_1)$), the impact of errors depends on the gravity difference being measured and the required accuracy. Good field practice, including routine calibration and use of multiple instruments for critical measurements, prevents degradation of survey results from this error source.

Instrument Noise

Thermal noise determines the detection limit of the sensor and is given by (e.g., Richter et al. 1995)

$$a_t^2 = \frac{25k_b T}{QmT_n} \left(\frac{(\text{ms}^{-2})^2}{\text{Hz}} \right)$$

where a_t is the rms noise equivalent acceleration spectral density, k_b is Boltzman's constant, T is absolute temperature, Q is the quality factor, m is the mass of the proof mass, and T_n is the natural period. For a metal spring LaCoste and Romberg earth tide gravimeter operating at 323 K with $Q = 1$, $m = 80$ g, and $T_n = 20$ s, the thermal noise is $a_t^2 = 7 \times 10^{-20} \text{ m}^2 \text{ s}^{-4} / \text{Hz}$ (Richter et al. 1995) and for a superconducting gravity sensor operating at 4 K with $Q = 0.14$, $m = 4$ g, and $T_n = 5$ s, the thermal noise is $a_t^2 = 5 \times 10^{-19} \text{ m}^2 \text{ s}^{-4} / \text{Hz}$ and could be a factor of 3 higher, depending on the extent to which the horizontal modes couple into the vertical (Van Camp 1999).

The thermal noise limit is therefore a significant design parameter for stationary gravimeters measuring in the frequency band dc–7 mHz where earth noise power spectral density can be lower than $10^{-19} \text{ m}^2 \text{ s}^{-4} / \text{Hz}$ (Ingate and Berger 2004).

Long-Term Drift

Long-term drift is a characteristic of all relative gravimeters and imposes constraints on the way in which instruments are

used. Values range from a few $\mu\text{Gal}/\text{year}$ for instruments with superconducting sensors (e.g., Crossley et al. 2003), $5 \mu\text{Gal}/\text{day}$ or more for metal spring sensors (e.g., Crossley et al. 2013) and up to several hundred $\mu\text{Gal}/\text{day}$ or more for survey gravimeters with quartz sensors (e.g., Bonvalot et al. 1998; Merlet et al. 2008). Drift is modeled as a function of time and removed from measurements as part of data processing. Model parameters for survey instruments are derived from repeat readings on base stations at different times during a survey. Absolute gravity readings obtained at the same site are used as a reference to verify the drift model of superconducting gravimeters (e.g., Van Camp and Francis 2007).

External Noise Sources

The effect of external inputs on the sensor can be reduced to acceptable levels by a number of approaches which are described below. These include shielding the sensitive elements, compensation, and filtering and reducing the input at its source through setup and choice of location and time.

Sensor Motion and Orientation

Motion of the gravity sensor can produce a response which is only distinguishable from the gravity signal by its frequency content. If the disturbing motion is outside of the signal bandwidth, then its effects can be removed by filtering, otherwise independent means must be used to determine the sensor motion and compensate for its effects. High frequency motion and vibration can excite higher order sensor modes which can couple into the fundamental mode (e.g., Block and Moore 1970).

The gravity sensor measures the components of gravity and acceleration that are parallel to its sensitive axis. To accurately measure gravity, the sensor is vertically aligned. Vertical misalignment of the sensor results in a component of gravity being measured which varies as the cosine of the angle. Sensor tilt can be actively controlled using a levelling platform or similar mechanism, or measured and then corrected in post processing (Van Camp et al. 2017).

Horizontal acceleration can produce “cross coupling” in sensors that have the proof mass in the form of a horizontal pendulum and feedback control which doesn't keep the mass at the zero position with sufficient accuracy (e.g., Torge 1989). Horizontal velocity causes centrifugal and Coriolis accelerations which combine to produce the Eötvös-effect (Torge 1989).

The relative magnitude of each of these error sources depends on the mode in which the instrument is operated:

Airborne gravity precision and spatial resolution are ultimately limited by the recovery of aircraft vertical position with GPS (e.g., Bell et al. 1999). This limit has been estimated to be around 1 mGal rms for an 80 s filter (van Kann 2004), an

estimate which is confirmed by actual measurements of aircraft acceleration with GPS (Wei and Schwarz 1995). Performance at this level has been reported for at least two airborne gravity systems (Studinger et al. 2008). One of these, the Sander Geophysics system, which is based on inertial-grade accelerometer sensors, is unaffected by turbulence up to 0.6 m/s^2 rms (Argyle et al. 2000).

In marine gravity, the ship moves relatively slowly on an approximately equipotential surface (Torge 1989) so there is no significant vertical acceleration in the signal bandwidth and the relatively high frequency acceleration caused by wave motion is removed by low pass filtering. Horizontal position and velocity, derived from GPS measurements, are used to compensate Eötvös-effects with sufficient accuracy to enable gravity anomalies of 0.2 mGal to be detected with a 0.5 km spatial resolution (LaFehr et al. 1992).

Survey gravimeters are affected by ground motion in the form of microseismic noise, cultural and wind noise, and earthquakes. Microseismic noise peaks in the range between 3 and 8 s (e.g., Ingate and Berger 2004) and has amplitudes as high as 1 mGal pp . (Laswell et al. 2010). Distant earthquakes produce signals with peak amplitude at a period of around 20 s (Ingate and Berger 2004). Cultural and wind noise is generally above 1 Hz (e.g., Wilson 1953) and depends on local conditions. The effect of these noise sources can be reduced with low pass filtering. Astatized (long-period) sensors have naturally lower sensitivity to this noise; however, proportional (short-period) sensors with digital filtering can produce readings with an rms noise level of a few μGal or less in most conditions (Scintrex 2019; Crossley et al. 2013).

Stationary gravimeters avoid cultural and wind noise through the choice of a quiet reading site (e.g., Torge 1989). Earthquakes often generate the signal that is being measured. Filtering is used to suppress signals outside the band of interest (e.g., Agnew et al. 1976).

Temperature, Pressure, and Magnetic Field

Sensitivity of spring-mass sensors to these inputs is largely determined by the material that the gravity sensor is constructed from. For example, the elastic suspension of metal spring instruments is made from a material with an elastic modulus that has low temperature sensitivity, but relatively high magnetic field sensitivity. Fused quartz is not sensitive to changes in magnetic field, but its elastic modulus has high temperature sensitivity.

The amplitudes of temperature, pressure, and magnetic field changes that reach the gravity sensor are reduced by control, sealing, and shielding, respectively. In addition, stationary gravimeters are often placed in environments where the temperature is extremely stable (e.g., Van Camp and Francis 2007). If residual changes reaching the sensor are significant, they are compensated mechanically or

electronically. In the Scintrex CG-3, CG-5, and CG-6 quartz instruments, the temperature is controlled to the m°C level and further compensated to the $\mu^\circ\text{C}$ level based on a temperature measurement close to the elastic suspension (Hugill 1990). In the metal spring LaCoste and Romberg instruments, residual pressure changes are mechanically compensated (Ander et al. 1999).

Superconducting penetration depth determines the temperature sensitivity of superconducting gravity sensors (Goodkind 1999), and the levitation force is directly proportional to magnetic field changes. The amplitude of temperature and magnetic field changes at the sensor are reduced to acceptable levels by controlling temperature to a few $\mu^\circ\text{C}$ and surrounding the instrument with a double μ metal/Niobium magnetic shield.

Transportation Effects

Changes in readings, often called tares; changes in drift rate; and elastic relaxation can all contribute to errors as a result of transportation. However, these errors can generally be avoided through good operating procedures. Careful handling and appropriate protection from shock and vibration (e.g., Hamilton and Brule 1967) can reduce or eliminate tares. Variable drift can be recovered by frequent base station reoccupation (e.g., Webring et al. 2004) and elastic relaxation is minimized in quartz instruments by maintaining vertical orientation during transport (e.g., Zumberge et al. 2008) and by waiting a fixed time after unclamping in metal instruments (e.g., Torge 1989).

Gravimeters

Some gravimeters in use today are listed in Table 3.

Summary

Relative gravimeters are based on one of four core technologies: spring-mass systems made from quartz or metal, superconducting sensors, or inertial-grade accelerometers. Performance requirements depend on whether instruments are to be used for surveys or in stationary or dynamic modes of operation. Useable sensitivity varies from $3 \times 10^{-2} \mu\text{Gal}/\sqrt{\text{Hz}}$ for stationary instruments operated in observatories to 0.5 mGal for dynamic gravimeters operated in aircraft. The defining characteristic of survey instruments is the capability to withstand acceleration and shocks during transport without sustaining changes in the reading value. Dynamic instruments must be able to produce data while moving and subject to large accelerations.

Gravimeters, Table 3 Some relative gravimeters currently in use

Gravimeter	Type	Sensor technology	Period	Displacement sensor	Feedback actuator	Reference
LaCoste and Romberg g meter	Survey	Metal spring-mass	Long	Optical, capacitive	Mechanical (electrostatic)	Webring et al. (2004)
Scintrex CG-3/5/6	Survey	Quartz spring-mass	Short	Capacitive	Electrostatic	Hugill (1990), Scintrex (2019)

Gravity Anomalies, Interpretation

Mikhail K. Kaban

Department 1: Geodesy and Remote Sensing, Sektion 1.3: Earth-System Modelling, Deutsches GeoForschungsZentrum Potsdam – GFZ, Potsdam, Germany

Definition

In geophysics *gravity anomalies* are generally defined as the difference between observed gravity field and the field of a reference model. Depending on the reference gravity model, two different types of anomaly variations are considered: *gravity anomalies* and *gravity disturbances*. The geodetic *gravity anomaly* is defined as the difference between gravity on the geoid and normal gravity on the reference ellipsoid (Blakely 1995; Heiskanen and Moritz 1967). On the other hand, the *gravity disturbance* is defined as the difference of the fields at the same point on the reference ellipsoid. It has been demonstrated that the gravity disturbances are more appropriate for geophysical purposes (e.g., Hackney and Featherstone 2003). In any case, it is necessary to take into account this difference in the interpretation. For more details see ► “Gravity, Data to Anomalies.” Here we use the general term “anomalies” for both types as traditionally accepted in geophysics.

The observed gravity anomalies reflect the effect of density variations relative to the homogeneous reference model. *Interpretation* of the gravity anomalies implies an estimation of these density heterogeneities. The density model should reproduce the observed gravity field, taking into account that the observations may be affected by measurement errors. A separate type of modeling, which may be also related to the interpretation, is an *enhancement* of the gravity anomalies. The observed field combines effects of various mass anomalies integrated over the whole Earth. Therefore, it is often difficult to select the anomaly, which relates to the object under study. The usual way to cope with the problem is to remove the effects, which mask the anomalies of interest (see also ► “Gravity Data, Regional: Residual Separation”).

Introduction

Density heterogeneity of the Earth, associated with thermal and compositional variations or with deflected boundaries separating layers of different density, is one of the main factors that control dynamic processes and deformations at both shallow and deep levels. Therefore, interpretation of the gravity anomalies or *gravity modeling* is one of the principal methods, which help to understand nature and origin of the

tectonic processes and the Earth's dynamics. On the other hand, gravity field is very sensitive to shallow heterogeneities, in particular related to mineral deposits. For this reason, gravity modeling is an important tool for both fundamental and practical purposes.

Formulation of the Problem

The relationship between the density distribution ρ and the gravity field g may be written as an operator equation:

$$A\rho = g, \quad (1)$$

where A is the integral operator. In Cartesian coordinates for a 3D body with density $\rho(x', y', z')$, this equation may be written as (Blakely 1995):

$$g(x, y, z) = \frac{\partial U}{\partial z} = -\gamma \iiint_{z' y' x'} \rho(x', y', z') \frac{(z - z')}{r^3} dx' dy' dz', \quad (2)$$

where (x, y, z) are the observation points, U is the gravitational potential, γ is the gravitational constant, and $r = \sqrt{(x - x')^2 + (y - y')^2 + (z - z')^2}$.

Therefore, the problem of determination of the density distribution ρ may be formulated as finding:

$$\min \left\{ \|A\rho - g_{obs}\|^2 \right\}, \quad (3)$$

where g_{obs} is the observed gravity anomaly.

Unfortunately, the problem of gravity data inversion is generally *ill posed*. The operator A has no continuous inverse A^{-1} ; thus the solution is neither unique nor stable. To overcome this principal weakness, Eq. 3 should be modified by adding a so-called regularization term Ω (Tikhonov and Arsenin 1977):

$$\min \left\{ \|A\rho - g_{obs}\|^2 + \alpha \Omega(\rho) \right\}, \quad (4)$$

where α defines strength of regularization. The regularization implies some a priori conditions imposed on the density distribution in order to limit a possible range of the solutions. If these conditions are sufficient, the problem becomes *well posed*.

There are basically two ways to obtain a unique and stable solution with the means of interpretation of the gravity anomalies. The first option implies considering simplified models, the parameters of which should be determined. An inclusion of a certain form in a homogeneous or stratified material, a thin layer with variable density, or an interface between two

layers with different density contrasts are the methods with which the number of unknowns are reduced and the problem is generalized. These models are adequate for modeling strong density contrasts, like the ocean bottom, the basement, and the crust–mantle interface, and are optionally used jointly with the concept of *isostasy*. The methods assuming a spatially restricted source are suited in the exploration of superficial bodies as ore bodies, diamond bearing Kimberlite cylinders, and salt domes. The methods using a density interface are used to define the ocean bathymetry from the gravity field or to determine the Moho, especially in remote areas where seismic studies are scarce or insufficient (e.g., Silva et al. 2006; Smith and Sandwell 1997; Van der Meijde et al. 2015). The other way to cope with the problem implies joint analysis of the gravity anomalies together with supplemental geophysical information, in particularly with seismic data that identify the basic structure of the Earth interiors. Using this method, it is possible to construct advanced models, which describe the structure of the Earth more reliably. Two basic interpretation techniques are used within this approach: forward method and inverse method (Blakely 1995) (see also ► “Gravity Method, Principles”).

Gravity Anomalies: Conditions and Enhancement

Spatial *resolution* of the gravity anomalies should be adapted to the scale and purpose of the study; it should be equal or better than the size of the smallest object of interest. *Local studies* range from meters to several tens of kilometers. They are chiefly intended to geophysical prospecting, archaeological, and construction purposes. It is also a useful tool to investigate local tectonics, for example, related to volcanic activity. If possible, gravity anomalies defined at the original observation points should be used for these investigations. It is desirable to remove a regional trend from the observed anomalies. It is clear from Eq. 2 that the gravity effect of any source rapidly decreases when we move this source to a greater depth. A useful approximation may be obtained from a spectral representation of the gravity field. A gravity effect of density variations at the depth Z having the wavelength L is reduced by the factor:

$$\exp(-2\pi Z/L) \quad (5)$$

compared to the effect of near-surface variations.

Regional studies range from tens to first thousands of kilometers. They include various tectonic applications. The required resolution of the gravity anomalies is within approximately $5'$ – $30'$. Since the original field contains sharp variation, a special attention should be paid to the data preparation. Normally, the observed values are averaged over the compartments that correspond to the grid used in the study. *Global studies* include the whole Earth and are intended to

investigate structure of the planet down to the core–mantle boundary as well as global mantle convection. The required data resolution normally ranges from 1° to 5° .

Enhancement of the gravity anomalies. A straightforward way to reduce the ambiguity of the gravity interpretation is to calculate the gravity effect of those structures, which are known from other geophysical methods, and to remove it from the observed anomalies. Then, the residual will highlight the gravity effect of “unknown” heterogeneities. *Bouguer gravity anomalies* represent the first step of the gravity “stripping.” However, this procedure may be extended using the data on the crustal structure obtained from seismic studies. Attempts to calculate residual “crust-free” gravity anomalies have been made since the first seismic profiles were measured, but a reliable 3D model could be constructed only after sufficient initial data on the crustal structure had been accumulated. One of the first maps of the residual gravity field covering a considerable part of North Eurasia was calculated by Artemjev et al. (1994).

After construction of 3D models of the crust based on seismic data, this method of the gravity interpretation has been extensively used over the last decade (e.g., Kaban et al. 2003). Detailed maps of sedimentary basins and their density structure are available from numerous prospecting surveys. A number of seismic data showing crustal structure down to the crust–mantle boundary (Mohorovičić discontinuity) have also significantly increased. Based on these data, a number of 3D crustal models with regional and global coverage have been compiled (e.g., Tesauro et al. 2008; Laske et al. 2013). Density distribution within the crystalline crust is determined based on the relationships between seismic velocity and density (e.g., Christensen and Mooney

1995). Then, it is possible to calculate gravity effect of the crustal layers and to remove it from the observed field. The modern calculation methods employ integral equations similar to Eq. 2 (also in a spherical case) and can provide any desirable accuracy (e.g., IGMAS, <http://www.gravity.uni-kiel.de/igmas/>). While doing these calculations, it is important to include the regions surrounding a study area. The distance, on which this effect might be important, may be estimated from Eq. 5. For the continental regions with deep crust–mantle boundary, this distance should be at least 500 km. One of the first global maps of the residual mantle anomalies is shown in Fig. 1 (Kaban et al. 2003). This map is extensively used in studies of the mantle structure and dynamics.

Forward Method

A gravity model is constructed using an iterative approach. This type of interpretation is used when velocity models obtained from seismic profiles are used to constrain the density model. An initial model is constructed based on a priori data and modeling assumptions. The initial structure is based on seismic boundaries, and seismic velocities are converted to densities. The model’s gravity anomaly is calculated and compared with the observed field. Then, the model parameters are adjusted using an iterative process to improve the fit between the modeled and observed anomalies. At the first stage, density of the seismic blocks is modified. If the fit is not sufficient, seismic boundaries might be changed as well. One example of such interpretation along the URSEIS profile crossing the Southern Urals is shown in Fig. 2 (Kimbell et al. 2002).

Gravity Anomalies, Interpretation, Fig. 2 2D gravity model for the URSEIS profile (Kimbell et al. 2002). The first number indicates density (Mg/m^3)

Inverse Method

In the inverse method, model parameters are automatically determined by solving Eq. 4. This technique is also used for joint interpretation of the gravity and seismic data. For the regional seismic profiles, it was developed by Strakhov and Romanyuk (1985), whereas for global studies based on tomography data, by Hager and O'Connell (1981). The idea of the method implies use of seismic velocities to stabilize the solution of Eq. 4. Instead of determining density variations in each grid point of the 3D model, a velocity–density relationship for selected blocks and layers should be introduced. This relationship may vary significantly; however, it is rather stable for similar compositions and physical conditions. Therefore, after selecting several blocks and layers, which are supposed to obey the same conditions, it is possible to determine a very limited number of the model parameters (velocity-to-density scaling factors for the specified blocks and layers). This provides the possibility to obtain a unique and stable solution of the inverse problem. A clear advantage of the inverse method with respect to the forward modeling is that it provides a possibility to quantitatively control sensitivity of the gravity anomalies to variations of the model parameters and their uncertainties.

The initial density model is usually produced by a simple linear conversion of the velocity disturbances into density variations. The initial scaling factors (c_j^0) are based on mineral physics and petrological data (j is the number of the selected layer or block). In the inversion they should be rescaled in a least squares adjustment. The inversion can be performed in both space and spectral (or spherical harmonic) domains. The scaling coefficients a_j (to rescale the initially adopted values) are estimated by minimizing the function (Kaban and Schwintzer 2001):

$$\chi^2 = \sum_i \cos \phi^i \left(dg_{obs}^i - \sum_j \hat{a}_j dg_j^i \right)^2 + \sum_j \alpha_j (\hat{a}_j - 1)^2, \quad (6)$$

where dg_j^i is the initial gravity effect of layer or block j at the surface grid point i characterized by the gravity anomaly dg_{obs}^i . $\cos \phi^i$ is a formal weight factor to account for the convergence of the meridians in the equal angular grid. It is not required in case of the equal space grid or spherical harmonic inversion. The last term is used to stabilize the solution. In this case it requires that the estimated scaling

factors should not be significantly different from the initial ones. α controls strength of regularization. Equation 6 leads to the normal equation system with a dimension equal to the number of the unknown scaling factors. In spherical harmonic domain, a similar equation can be derived for each set of coefficients for specific spherical harmonic degree/number, which can be solved separately under certain conditions (Hager and O'Connell 1981).

In global studies this technique is used for interpretation of both geoid and gravity anomalies. Geoid is more sensitive to the effect of deep interiors, whereas a use of the gravity anomalies provides better resolution, especially for the upper mantle (e.g., Simmons et al. 2009). An example of such study is shown in Fig. 3. The velocity-to-density scaling factor is determined for the oceanic upper mantle in the joint inversion of the residual mantle gravity anomalies and seismic tomography (Kaban and Schwintzer 2001). The obtained density–velocity ratios for the subcrustal layer (down to 75 km) and for the deep part of the oceanic upper mantle (below 225 km) are very close to the ones predicted from the mineral physics analysis. However, for the oceanic layer involving the depths 75–225 km, a significantly lower density–velocity ratio is obtained. This may be explained by a compositional layering: dry, partially depleted peridotite residuum underlain by “damp” fertile peridotite and separated by the G discontinuity at a depth of about 70 km. This result is important for geodynamic modeling. It evidences that the base of an oceanic lithosphere plate is defined by a compositional rather than thermal boundary layer or, at

least, the base is strongly influenced by a compositional boundary.

In recent years, it has been developed a new integrative technique for construction of 3D density models of the upper mantle. In addition to the residual mantle gravity anomalies and seismic tomography, this method employs the residual topography that is the topography, which is supported by the mantle density heterogeneity. The residual gravity and topography are controlled by the same factors but in a different way (e.g., depending on depth and horizontal dimension of the heterogeneity.) This enables us to locate the position of principal density anomalies in the upper mantle (Kaban et al. 2016). One example of such inversion for the Middle East is shown in Fig. 4.

Summary

Due to new interpretation techniques and increased computer power, most of the computational problems related to the forward and inverse gravity modeling, which caused big problems even recently, are solved. For example, the direct computations using Eq. 2 may be performed for on large grids taking into account 3D density variations. Also a principal difference from the early stage period is that the interpretation of the gravity anomalies is performed now in combination with other methods. The most profitable results are obtained from the integrative interpretation of the gravity and seismic data. Further combination with geothermal data provides the possibility to separate the effects of temperature and composition variations within the Earth. The obtained density models are used in various applications. This information is essential for a geodynamic modeling that results in determination of the mantle flows, tectonic forces moving the lithosphere blocks, and stress distribution in the crust and mantle at both regional and global levels. Interpretation of the gravity anomalies is also widely used in geophysical prospecting. In some situations the seismic investigations fail to give results, for example, when a high-velocity layer masks the underlying low-velocity layers. Here the gravity and magnetic investigations are the principal means to obtain information on the underlying structure.

Two principal problems should be a key issue for the gravity modeling in future. As it was shown, reliability of the gravity modeling depends on additional data used in the interpretation. Therefore, it is necessary to bring together data from various disciplines, which might be used in construction of integrative interpretation models. Geophysicists just started approaching this ultimate goal. The second principal issue is improvement of the technique for integrative interpretation. In particular, special attention should be paid to solution of nonlinear inverse problems and to ultrahigh dimension problems.

Gravity Anomalies, Interpretation, Fig. 3 The velocity-to-density scaling coefficients adjusted for “normal” and “anomalous” oceanic areas, respectively, compared with the result for the whole oceanic area. Only the scaling coefficients and standard deviations for the upper mantle are shown, but the inversion was performed for the whole mantle (Kaban and Schwintzer 2001)

Synonyms

Gravity: spectral methods; Potential field transforms

Definition

Spectral analysis	Estimation and analysis of global frequency content of a signal, assumed stationary, most often using the Fast Fourier Transform (FFT).
Potential field transformations	Process of converting gravity (or magnetic) survey data into a new and physically meaningful form to facilitate its geological interpretation.
Euler and Werner deconvolution	Methods for automatically estimating depths to sources from gravity (or magnetic) survey data.
Wavelet analysis	Estimation and analysis of local frequency content of a non-stationary signal, using a wavelet transform (WT).

Introduction

The use of spectral analysis to interpret gravity anomalies goes back to the 1930s, but the modern approach in terms of the Fourier transform (FT) was developed in the 1960s and 1970s. Most of the methods are equally applicable to magnetic data, which is their more common area of use because of the huge volume of aeromagnetic data now available. Here we will not generally distinguish between the two, though the magnetics case is complicated by the fact that the field and magnetization directions are not in general the same or vertical. Blakely (1995) provides an excellent introduction to the subject, which he divides into two basic aspects: *spectral modeling* and *potential field transformations*.

In spectral modeling, the major advantage of working in the wave-number ($k = 2\pi/\lambda$) domain, after Fourier transforming the data, is that it offers simplifications and insights into the relation between anomalies and their sources. For example, the FT of the gravity anomaly over a thin horizontal layer of variable surface density $\sigma(x, y)$, at depth d , is simply the product of the FT of σ with a constant times $e^{-|k|d}$. Other models similarly separate into products of factors.

Potential field transformations can be carried out in the space domain by either numerical integration or convolution, but in the wave-number domain, the simple forms of the transformations offer considerable insight. They include upward and downward continuation, and vertical and horizontal derivatives, all of which have their uses in enhancing resolution and separating anomalies.

Both aspects were made practical by the development of the FFT, though it should be noted that there are important differences between the theoretical (continuous, infinite) FT and the (discrete, finite) FFT – see below.

The FT assumes that the statistical properties of the data do not vary spatially (i.e., the data are *stationary*), which may not be the case with real data. The wavelet transform allows spectral analysis without this assumption and therefore promises improvements over the FT.

Spectral Modeling

Many applications of spectral modeling have been devised: for example, Blakely (1995) gives expressions for the FT of the anomalies for a number of simple models. Here just two of the more commonly used methods will be described.

Parker (1972) extended the simple horizontal layer model (mentioned above) to the case of a layer bounded by irregular top and bottom surfaces. This allows the very rapid calculation (via the FFT) of the gravity anomaly over a square grid for such common cases as sedimentary basins, marine Bouguer corrections from bathymetry, and Airy isostatic corrections from topography.

The method of *statistical models* was pioneered by Spector and Grant (1970) for interpreting magnetic data. In the gravity case, the method assumes that the anomalous field results from an *ensemble* of dense vertical prisms where each of the model parameters is randomly distributed with uniform probability about a mean value. As mentioned above, the FT of the anomaly of each prism is the product of several factors, notably a depth factor ($e^{-|k|d}$), a depth extent (t) factor ($1 - e^{-|k|t}$), and a size factor (a function of the width and breadth of the prism). The method employs the radial *power spectrum* of the observed anomaly, i.e., averaged over concentric annular rings in the (k_x, k_y) plane, implying that isotropy is assumed. The theoretical power spectrum for the ensemble of prisms is the product of the *ensemble averages* of the square of each of the above factors. If the ranges of the parameters are not too large, the ensemble averages will approximate the factors for their mean values. At wavelengths much larger than the body dimensions, the size factor tends to a constant. This is equivalent to assuming a dipole, rather than prism, model. Then the mean depth and depth extents can be estimated by plotting the logarithm of the power spectrum. The depth factor gives a straight line of slope $-2d$ at medium to large k , and the depth

extent factor causes this slope to decrease as k decreases, giving rise to a maximum. Thus in principle the mean values of both d and t can be estimated. The basic problem with the method lies in knowing to what extent the assumptions are justified. If the body dimensions are not small compared to the wavelengths, then it may be possible to estimate their average values, calculate a size factor, and hence correct the power spectrum. But if parameter values are not completely random and uncorrelated, but are self-similar or fractal (for which there is some evidence) then the power spectrum will be proportional to a power of k , invalidating depth estimates. See Blakely (1995) for references.

Potential Field Transformations

Transformations of gravity and magnetic data have a long history in applied geophysics (e.g., Grant and West 1965), since their utility was realized long before they could be easily and accurately applied. Three examples of transformations that are commonly used in gravity interpretation are listed below with their uses.

- (a) Vertical derivative: largely eliminates the regional and improves resolution.
- (b) Upward continuation: very efficiently attenuates nearsurface effects; used as a standard “separation filter” (Jacobsen 1987).
- (c) Downward continuation: enhances resolution, i.e., it allows the separation of closely spaced or overlapping anomalies; approximate inversion for a uniform density layer.

These operations depend on a theorem from potential theory stating that the gravity potential caused by any 3D density distribution is identical to that of a thin layer of mass spread over one of its equipotential surfaces. This is *Green’s equivalent layer* (Blakely 1995). For example in the case of upward continuation of gravity data measured on a level surface at height z_0 to a second level surface Δz above it, the equivalent layer is taken to lie in the measurement plane. The theoretical formula for the upward continued field at a point $P(x, y, z_0 + \Delta z)$ is an integral over the complete (and infinite) plane measurement surface since each point in that plane acts as an element of mass. This integral can then be written as a convolution of the data with $\Delta z/r^3$, where r is the distance from point Q in the z_0 plane to point P . Fourier transforming this expression reveals that the FT of the upward continued data is the product of the FT of the measured data and $e^{-|k|\Delta z}$, where $k = \sqrt{(k_x^2 + k_y^2)} = 2\pi/\lambda$ (radians/m). This simple view of upward continuation as a filter with wave-number response $e^{-|k|\Delta z}$ offers physical insight that explains immediately why

the operation is effective at attenuating (exponentially) near-surface density anomalies.

The responses of some other common transforms are: downward continuation through height Δz , $e^{|k|\Delta z}$; vertical derivative, $|k|$; vertical integral (potential), $1/|k|$; x-derivative, ik_x . One transform that is particularly useful in mapping is the horizontal gradient amplitude (HGA): $\sqrt{[(\partial g/\partial x)^2 + (\partial g/\partial y)^2]}$, whose maxima occur vertical contacts. Another is the analytic signal amplitude (ASA): $\sqrt{[(\partial g/\partial x)^2 + (\partial g/\partial y)^2 + (\partial g/\partial z)^2]}$.

Using the FFT is much faster than either numerical integration or convolution, except for very small arrays of filter coefficients such as the centered difference approximation generally used for horizontal derivatives. It also implies certain requirements of the data (usually met by *preprocessing*) because the FFT differs from the continuous FT in important ways (e.g., Blakely 1995). First, it is discrete, with (1D) data spacing Δx , which means that the FFT is periodic, repeating itself every $k = 2\pi/\Delta x$. This leads to aliasing of wave numbers outside the band defined by the *Nyquist* wave number $k = \pm \pi/\Delta x$ into the FFT at smaller wave numbers, unless the data are band limited. The preprocessing can include an antialias filter to ensure this. Second, the FFT is a finite summation over a data length $N\Delta x$, rather than the infinite integral of the FT, and hence implicitly assumes that the data set is periodic, infinitely repeating itself or, equivalently, circular with the last point next to the first. To avoid first order discontinuities at the data edges (which would lead to the Gibbs effect), the preprocessing then includes extending the data in such a way as to produce a smooth transition between neighboring repetitions. With these precautions, the FFT method is capable of accurate results for most transformations, unless they require amplification of wave numbers that are not present in the data, due to it's being either too short (and therefore lacking low wave numbers – below $1/N\Delta x$) or digitized with too large an interval Δx , or otherwise inaccurate.

A modern example of an application that uses a transformation via the FFT occurs in processing data from the Falcon™ airborne gravity gradiometer system, whose sensor measures the horizontal curvature components (Dransfield and Lee 2004; Nettleton 1976). The easiest way to convert these components to the more familiar vertical gradient is to grid them and then apply a complex transformation via the FFT.

Euler and Werner Deconvolution

These are approximate inversion methods for automatically locating the depths to the tops of multiple sources. The principles of both methods are dealt with by Blakely (1995). The name is by analogy with seismic deconvolution where seismic reflection arrivals are converted into impulses

representing reflectors. The methods are similar in many ways, but Werner's method in its original form is only applicable to aeromagnetic profile data, whereas the Euler method can be applied to profiles or grids of magnetic or gravity data. However, generalizations of the methods to different types of gradient data have been made and it has been shown that Werner's method using the analytic signal is in fact a special case of Euler deconvolution (Nabighian and Hansen 2001). Werner's method will not be described in detail, but his idea was to linearise the magnetic anomaly on a profile perpendicular to a thin dipping dyke, which contains four unknowns; hence any four measurements along the profile will give four simultaneous equations which can be solved for the position and depth of the top of the dyke.

Euler Deconvolution

Euler deconvolution (Thompson 1982; Reid et al. 1990) is very similar but uses a more general equation than that of a dyke, namely Euler's equation, which can approximately model the behavior of many different simple sources. Euler's equation is satisfied by any homogeneous function $f(x, y, z)$ of degree n (one that is invariant under scaling) and can be written:

$$x \frac{\partial f}{\partial x} + y \frac{\partial f}{\partial y} + z \frac{\partial f}{\partial z} = -nf$$

For example, $f = 1/r$ satisfies this equation with $n = 1$, implying that so does the potential of a point mass. The degree n is called the *structural index*, and defines the attenuation rate of the field f due to the particular source. Examples for gravity field anomalies are (FitzGerald et al. 2004): point mass, 2; line mass, 1; finite step, 0; contact, -1 . Reid et al. (1990) showed that certain extended bodies like thin dipping sheets (e.g., irregular dykes and sills) can also satisfy Euler's equation, but this is not generally true.

In practice, the gradients are generally calculated from a grid of gravity anomaly data as described above. In order to locate the center of a body (x_0, y_0, z_0) from survey data, it is necessary to replace (x, y, z) in Euler's equation by $(x-x_0, y-y_0, z-z_0)$. Implementation of a grid Euler method follows that of a least squares version of Werner's method, where simultaneous equations are formed from a square array (or window) of grid points of between 3×3 and 10×10 equations and a LS solution found for x_0, y_0, z_0 and a background field B (i.e., f is replaced by $f-B$ on the RHS of the equation). In this case, n cannot be solved for, but must be assumed and the normal procedure is to try several values and select the one giving the most consistent results. The procedure is repeated for all points of the grid, and may generate large numbers of solutions, many of them unrealistic because the assumption of a simple source with constant n for each window is invalid. In practice, most of these solutions can be

easily eliminated by selecting only those that (a) have standard deviations for x_0 , y_0 , z_0 (obtained from the LS solution) of <5–10% of the depth and (b) fall within the window. Another useful way to restrict the number of solutions is to apply the method only close to localized anomalies as defined, for example, by areas of positive curvature of the horizontal gradient (HGA).

Extended Euler Deconvolution

For the 2D case, Mushayandebvu et al. (2001) discovered a second equation, similar to Euler's, for homogeneous functions that are also invariant under rotation. They rewrote the two equations for the particular cases of a magnetic contact and a thin dyke so that their right hand sides include terms involving the susceptibility and dip. Their *extended Euler* method finds solutions satisfying both equations that yield susceptibility and dip estimates as well as x_0 , y_0 , and z_0 . Nabighian and Hansen (2001) then showed that the additional equation could be written in terms of the *Hilbert transform* of f (e.g., Li 2006) which shows that it is just Euler's equation applied to the Hilbert transform. They further extended the new equation to 3D, in terms of generalized x- and y- Hilbert transforms (which can be represented and calculated as potential field transformations with wave-number domain responses $H_x = -ik_x/|k|$ and $H_y = -ik_y/|k|$, as shown by Nabighian 1984). It has been found that, assuming a value for the structural index and using all three equations for the anomaly data and their x- and y- Hilbert transforms gives better-constrained solutions than using just one equation for the anomaly data. Moreover, the new equations allow a number of other possibilities, including solving for the structural index (FitzGerald et al. 2004).

Tensor Deconvolution

Although gradiometer data can be used with advantage in Euler deconvolution, Mikhailov et al. (2007) show that with full tensor ("FTG") data it is possible to devise a method that dispenses with data windows and locates a source beneath each measurement point based on invariants calculated from the five independent tensor components. They suggest that since this method appears to locate the centers of bodies, whereas Euler deconvolution locates their edges, the methods should complement each other.

Wavelet Analysis, with Advantages and Limitations

Introduction

The wavelet transform (WT) was developed in the early 1980s, in an attempt to better understand the frequency content of seismic signals (e.g., Grossman and Morlet 1984). Whereas the Fourier transform (FT) provides the amplitudes

and phases of all harmonics present in the entire signal (a *global spectrum*), the WT yields these quantities at each time (or space) location of the signal (*local spectra*). For instance, the WT of Beethoven's Ninth Symphony tells one when to play C major, or when to play D minor chords. The FT, however, merely tells the musician that C major and D minor chords occur somewhere in the symphony (e.g., Antoine et al. 2004).

For this reason, the WT is superior in analyzing the harmonic constituents of *non-stationary* signals, that is, signals whose harmonics vary throughout the signal. The application to the Earth's potential fields is evident. The depth, spatial extent, and density/magnetization contrast of sources vary widely over a given region, leading to anomaly maps with clear differences in spectral characteristics from place to place. The wavelet power spectrum, or "*scalogram*," of such a map thus quantifies the relative power of each harmonic at each spatial location; in contrast, the Fourier power spectrum shows only the total harmonic composition of the map.

The WT has two distinct forms, termed "continuous" and "discrete." Unfortunately, there is no analogy between this use of the terms and their use with the FT: as mentioned, the continuous Fourier transform (CFT) is an integral equation applied to continuous analytic formulae; the discrete Fourier transform (DFT) is its specialization to discretely-sampled signals. Both CFT and DFT, however, use the same *basis functions*, the complex exponentials (sines and cosines). However, with the discrete and continuous wavelet transforms (DWT and CWT, respectively), the names "discrete" and "continuous" apply not to the signal, but to the basis functions (the wavelets). So both CWT and DWT can be applied to discretely sampled signals, and the difference between them lies (mainly) in the wavelets.

Wavelets, whether discrete or continuous, differ from the basis functions of the FT (infinitely or quasi-infinitely extending sinusoids and cosinusoids) in that they are *localized* in space (or time). That is, while they are oscillating functions (with zero mean value), their amplitude decays rapidly with distance (or time) from their center. It is this feature which localizes the wavelet spectra to a region surrounding the point of interest. Contrast this with the DFT, where the complex exponentials maintain their amplitude over the whole study area, rendering localization impossible (though see below). However, a high degree of localization in the space (or time) domain results in a poorer degree of localization in the wave-number (or frequency) domain. This property is referred to as the *uncertainty relation* of spectral analysis, by analogy with Heisenberg's uncertainty principle of quantum mechanics. In the spectral case, the more localized the position (small Δx), the higher the uncertainty in the wave-number content of the signal at that location (large Δk); and vice versa, according to:

$$\Delta x \Delta k \geq 2\pi$$

For the DFT, since the Fourier transform of a sine wave is a delta-function (i.e., a spike in the frequency domain), Δk is very (infinitesimally) small and precise, whereas Δx is very (infinitely) imprecise. For the WT, there exists a trade-off between Δx and Δk according to the *scaling* of the wavelet.

It is this scaling that allows harmonic analysis. First, the WT of a given signal is a space (or time) domain convolution of the signal with scaled versions of a mother wavelet, giving *wavelet coefficients* at that scale. When the *wavelet scale* is large, the wavelets are stretched (in space or time), and the convolution yields the low-wave-number (or frequency) components of the signal; when the scale is small the wavelets are squeezed, and the convolution returns the high-wave-number (or frequency) components. However, the uncertainty relation means that large-scale wavelet coefficients tend to be spatially (or temporally) imprecise but spectrally precise, while small-scale coefficients will have the opposite properties.

The difference between the CWT and DWT lies in the choice of scales. In the DWT, the scales are chosen so that the wavelets are orthogonal. This naturally limits the range of scales to the minimum possible without loss of information; a property which is obviously preferable for image compression (e.g., Antoine et al. 2004), and means that the signal can be reconstructed very rapidly from the wavelet coefficients. The scales in the CWT, on the other hand, are not constrained, and the wavelets are hence non-orthogonal. This, though, offers redundancy in the wavelet coefficients which can be put to good use in analysis and interpretation, though reconstruction of the signal is slower.

The CWT and Windowed Fourier Transform

There are many kinds of discrete and continuous wavelet, each having certain properties that prove useful in a variety of applications. For instance, Morlet wavelets yield global spectra that best approximate those from the Fourier transform (Kirby 2005), while Poisson wavelets have a close relationship with the Laplacian operator, lending themselves to potential field applications (e.g., Hornby et al. 1999). Furthermore, wavelets may be defined in N dimensions for analysis of N -dimensional signals; in geophysics, the most commonly used are 1D and 2D wavelets. Wavelets may also be complex or real-valued: 2D complex wavelets such as the Morlet wavelet are anisotropic, while 2D real wavelets, such as the Derivative of Gaussian wavelets, are isotropic. Torrence and Compo (1998) provide a description of several 1D continuous wavelets, while Kirby (2005) discusses various 2D continuous wavelets.

The windowed Fourier transform (WFT) is also often used to recover local spectra from a signal. In this, the basis functions are windowed complex exponentials; e.g., the Gabor transform uses a Gaussian window which slides over

the signal. In the WFT, while the frequency of the complex exponential can increase or decrease, the window width (Δx) is fixed, meaning a fixed uncertainty in frequency, by the uncertainty relation. With the CWT, however, the window width (and hence frequency uncertainty) is variable (and directly related to wavelet scale). Hence, while the WFT has its uses, it is in general inferior to the CWT for several reasons, two of which are: (1) the WFT is not as good at analyzing signals with a large bandwidth (Foufoula-Georgiou and Kumar 1994); and, (2) it is not as good as resolving closely spaced spikes or discontinuities (Addison 2002).

Applications

The advantage of being able to estimate local, as opposed to global, power or phase spectra has seen the WT applied to many disciplines, not just the Earth sciences. Indeed, a 10-s Scopus search yields over 58,000 articles with “wavelet” in the abstract, with over 4,000 published in 2009 alone. Foufoula-Georgiou and Kumar (1994), Kumar and Foufoula-Georgiou (1997), Addison (2002), and Antoine et al. (2004) discuss many. For example, Moreau et al. (1997) and Hornby et al. (1999) show the usefulness of the CWT for location and edge-detection of sources within potential field data, and subsequent inversion of the wavelet coefficients, by considering the vertical variation of the field and its horizontal derivatives. Ridsdill-Smith and Dentith (1999) also tackle derivatives, but they use the DWT which enables localized frequency filtering. In another application of the CWT, Panet et al. (2006) reveal density anomalies below Pacific island volcanoes from the new satellite gravity data. And Kirby and Swain (2009) use the CWT to estimate spatial variations in lithospheric elastic thickness via a coherency analysis in the wavelet domain. Finally, there are several types of spherical, rather than planar, wavelet transform, which lend themselves to studies in geodesy (e.g., Klees and Haagmans 2000; Keller 2004; Chambodut et al. 2005).

Summary

This contribution outlines the theory and practice of a number of methods for rapidly processing gravity data that are in the form of a grid. The term “processing” here includes transformations, spectral estimation and modeling, and “deconvolution” to produce depth estimates. These are all widely used methods that are equally applicable to grids of aeromagnetic data. We also introduce the continuous wavelet transform which has many potential applications in gravity processing, few of which appear to have been widely used as yet.

A more extensive review of the gravity method, with comprehensive reference list, can be found in Nabighian et al. (2005).

Synonyms

Gravity effect of shallower and deeper bodies; Isostatic anomaly

Definition

<i>Observed Bouguer gravity</i>	Gravity field after corrections for drift, free-air, Bouguer, terrain, and latitude.
<i>Regional gravity anomaly</i>	Gravity anomaly due to deeper and broader structures.
<i>Residual gravity anomaly</i>	Gravity anomaly due to shallower bodies.
<i>Isostatic anomaly</i>	Isostasy corrected gravity anomaly.
<i>Interpolating or shape function</i>	The weighting factors for ground element covering the survey space for the computation of regional.

Introduction

The observed Bouguer gravity anomalies consist of two components – a regional component and a residual, that can be expressed by a simple relation:

$$\begin{aligned} \text{Observed Bouguer gravity field} \\ = \text{Regional gravity field} + \text{Residual gravity field} \end{aligned}$$

Commonly, the regional Bouguer gravity anomaly is the longer wavelength field due to deep sources, whereas the residual Bouguer gravity anomaly corresponds to short wavelength fields of shallower bodies. The short wavelength field dies off with depth.

However, in practice, the terminology of a regional gravity anomaly varies according to the target of the investigation and therefore does not necessarily refer to the fields generated at lower crustal depths. If the target is a mineral deposit located at the depths of 100–200 m, the basement rocks will form the regional structure. In case of hydrocarbon accumulation, the target sources are a few kilometers deep, and the regional field is generated by the rocks at the base of the sedimentary columns. The studies involving large-scale structures like subduction zones and large sedimentary basins, the regional field originates at lower crustal depths or still greater depths at Moho.

The regional and residual anomalies, therefore, are relative terms. These vary from problem to problem, and from place to place. The early workers like Griffin (1949), Elkins (1951), Nettleton (1954), Roy (1961), Steenland (1962), and Skeels (1967) viewed regional and residual from this view-point. For a regional gravity survey on a continental scale, the concept of isostasy is evoked (Jachens and Griscom 1985; Blakely 1995; Chapin 1996) to compute regional and isostatic anomalies.

In problems where the target bodies occur at shallower depths, the deeper regional field masks the response of the shallower targets and effectively acts as a noise. On the other hand, when the target body lies at greater depths, the response of shallower bodies becomes noise.

The above discussion points to the fact that it is important to separate regional and residual gravity anomalies. In effect, regional and residual gravity separation is a filtering process, and it enhances the noise-to-signal ratio. This step is essential for a precise quantitative interpretation.

It may be noted that the gravity method was first used in Geodesy. The geodesists assumed the Earth to be an ellipsoid for the processing of the Bouguer gravity data. Later on, the geophysicists used geoid as the reference surface for processing of Bouguer gravity data. Therefore, Bouguer anomaly used by geophysicists is different from that used by geodesists. Of late, there is an attempt to define gravity anomaly that

can be used by both groups (Hackney and Featherstone 2003; Hinze et al. 2005). The processing techniques are valid for both the datums. Here, we are dealing with Bouguer gravity anomaly from the view point of the geophysicists.

Regional-Residual Separation

The regional-residual separation is essentially a filtering process and is carried out broadly by two techniques: (i) graphical and (ii) analytical. The graphical method is not used these days anymore. It has only historical importance. In this method, the regional is obtained by visually smoothing the anomaly curve. The success of this approach depends on the experience of interpreter and his knowledge about the geology of the area.

Analytical Methods

The analytical techniques are developed both in space- and frequency-domain. Starting from simple four-point and nine-point averaging, Griffin's center-point-and-one-ring (1949), Agocs' least-squares (1951), Grant's statistical (1954) to polynomial fitting (Coons et al. 1967; Rao et al. 1975; El-Batroukh and Zentani 1980; Belthrao et al. 1991; Agarwal and Shivaji 1992; Leao et al. 1996), upward and downward continuations, and second derivative techniques are in space-domain. Mickus et al. (1991) has developed an algorithm using the minimum curvature technique to separate the regional and residual components.

Another approach is to build a density model of the deep-seated structures with parameters obtained by independent data and methods like seismics, aeromagnetism, fractals, spectrals, etc. and to compute their gravity effects. The field generated by these deeper sources is subtracted from the observed Bouguer gravity field to obtain the residual gravity anomalies. This approach developed at USGS employs the theory of isostasy and is frequently used to compute residual isostatic anomalies (Jachens and Griscom 1985; Blakely 1995; Lowrie 1997). A new deterministic method based on Airy-Heiskanen isostatic model had been developed by Chapin (1996). This technique assumes that the topography is fractal. The algorithm used in this technique inverts the present-day elevations to determine the depth to the base of the crust. This depth is then used as input to a 3-D gravity model that computes the gravity response (regional) of the crust. The regional term is then subtracted from the Bouguer gravity to yield the final isostatic residual.

In the frequency domain, high-pass, low-pass, and band-pass filtering techniques (Naidu 1968; Ulrich 1968; Cordell

1985; Pawlowski 1994) have been developed for regional and residual resolutions. Green's concept of an equivalent-source layer is invoked by Pawlowski (1994) to construct a data adaptive, zero-phase, Wiener band-pass filter for regional–residual separation (Pawlowski 1994), wherein the phase shift of the filtered signal is nullified by using a pair of cascaded low-pass and high-pass filters such that the phase lag caused by the low-pass filter is compensated by the phase lead introduced by the high-pass filter. The observed gravity field's Fourier power spectrum is modeled with two Green's equivalent source layers, one equivalent layer for the shallower geological sources (residual field) and another for the deeper geological features (regional field).

Possible Drawbacks in Regional Computation

In all the above-mentioned analytical techniques, the Bouguer gravity values over the anomalous zone(s) enter into the computations. Many investigators (Skeels 1967; ZurFluch 1967; Ulrich 1968; Leao et al. 1996; Ojo and Kangkolo 1997) have discovered that these techniques are not free from inaccuracies. In Griffin's (1949) center-point-and-one-ring method, the center point of the ring, which represents the regional field, moves over the entire survey space, including the anomalous zone. When the gravity values are picked up from one such anomalous zone for averaging, a small residual still remains, that is mixed with the regional anomaly. Besides this, the radius optimum choice is crucial to obtain the proper residual. Leao et al. (1996) pointed out that “any attempt to model a complex regional anomaly by a higher-order polynomial will force the polynomial to represent part of the residual field, thereby distorting the estimated regional field.” In case of the two most used techniques, both least-squares (Agocs 1951; Coons et al. 1967; El-batroukh and Zentani 1980; Leao et al. 1996) and spectral methods (Naidu 1968; Ulrich 1968; Cordell 1985; Klasner et al. 1985; Pawlowski 1994), the residual field is assumed to be zero-mean. Ulrich (1968) and Leao et al. (1996) observed that a departure from this assumption may contaminate the residual field through pseudo anomalies.

New Approach Based on Finite Element Analysis

A new space-domain operator, based on finite element concept (FEM), has recently been developed by Mallick and Sharma (1997, 1999) and applied to a variety of research problems (Sharma et al. 1999; Mallick et al. 1999; Mallick and Vasanthi 2001; Vasanthi and Mallick 2001, 2005; Kannan and Mallick 2003; Vasanthi and Sharma 2006). In addition to

these original studies, many other investigators have gained benefitted from this new technique (Kaftan et al. 2005; Agarwal and Srivastava 2010; Ekinci 2010; Ekinci and Yigitbaş 2012, 2015; Bruno et al. 2017; Kumar and Puneekar 2018).

This method is altogether different from all existing techniques in the sense that the observed gravity values over the anomalous zones in the survey space do not contribute to the regional computations. This technique is robust, well-performing, and not site-specific and overcomes most of the drawbacks encountered in the existing analytical methods.

The procedure to compute the regional field by FEM is as follows.

Given a gravity survey, a rectangular or square element is superimposed on it in order to have the maximum coverage that includes all zone(s) of interest. The ground elements for the computation of the regional field can take different sizes, shapes, and orientations. Figure 1 shows (a) four-node linear, (b) eight-node quadratic, (c) nine-node elements, corresponding to interpolating functions (or element shape functions) which are respectively linear, quadratic, and cubic. Figure 2a, b show a few higher order elements, such as (a) 12-node and (b) 16-node. Additionally, a very useful seven-node element is shown in Fig. 2c. It is an irregular element used conveniently to avoid any anomalous zone falling on any side of the ground element. In the case of irregular element, the interpolating function is specially defined in order to distribute the weights among seven nodes.

As in the finite element analysis (Cheng and Yeo 1979; Zienkiewicz 1979; Cook 1984), the field variable is assumed to be a weighted sum of discrete values at the vertices or nodal points of the element. The regional gravity field in the present case is defined in a similar manner and is expressed as:

$$g(x, y) = \sum_{i=1}^r N_i(x, y) g_i \quad (1)$$

where $N_i(x, y)$ are the shape functions, acting as weighting factors, r is the number of nodes in the element, and g_i are the observed gravity values at the nodes of the element. In the present case, $g(x, y)$ represents the regional field. The element nodes lie away from the anomalous zone(s) present in the survey space. The interpolating functions at different nodes are shown later at the end of this section.

The procedure to compute the regional field is explained with the help of an eight-node quadratic element.

Figure 3a represents an eight-node element in the x – y real space, i.e., the gravity survey space. The center is located at x_c, y_c with sides $2a$ and $2b$ are parallel to x - and y -axes, respectively.

Gravity Data, Regional-Residual Separation,

Fig. 1 Various types of elements: (a) linear, (b) quadratic, and (c) nine-node. Solid circles are nodes of the element

**Gravity Data, Regional-Residual Separation,**

Fig. 2 Various types of elements: (a) cubic, (b) sixteen-node, (c) seven-node. Solid circles are nodes of the element

The ground element in the survey space may be of any size and may have different orientation. Therefore, there is a need to standardize the element by substituting it by a non-dimensional element. This is achieved by the following simple substitutions:

$$\xi = \frac{(x - x_c)}{a} \quad \text{and} \quad \eta = \frac{(y - y_c)}{b} \quad (2)$$

These nondimensional coordinates ξ and η vary between -1 and $+1$. In other words, the ground element of any size and orientation is replaced by ξ - η reference space as shown in Fig. 3b, the reference space is a square element. The nodes 1 through 8 in the ξ - η reference element and the nodes of the element in x - y real space have one-to-one correspondence.

This transformation (i) simplifies the computational scheme, (ii) defines the weights, without ambiguity, in terms

Gravity Data, Regional-Residual Separation, Fig. 3 (a) Eight-node element in x - y real space. (b) Eight-node element in ξ - η reference space

of shape functions, and (iii) facilitates to encompass survey space of any size and of any orientation.

With the substitutions suggested in Eq. 2, the regional gravity $g_{\text{reg}}(\xi, \eta)$ at any point (ξ, η) in the reference element can be expressed as:

$$g_{\text{reg}}(\xi, \eta) = \sum_{i=1}^r N_i(\xi, \eta) g_i, \quad (3)$$

where the weights, $N_i(\xi, \eta)$, are the shape functions of the element and r is the number of nodes. For example, in case of the 8-node quadratic element, r is equal to 8 and the shape functions are given by:

$$N_i(\xi, \eta) = \frac{(1 + \xi \xi_i)(1 + \eta \eta_i)(\xi \xi_i + \eta \eta_i - 1)}{4} \quad (4)$$

(for corner nodes, $i = 1, 3, 5, 7$)

$$N_i(\xi, \eta) = \frac{(1 - \xi^2)(1 + \eta \eta_i)}{2} \quad (5)$$

(for mid-side nodes, $i = 2, 6$)

$$N_i(\xi, \eta) = \frac{(1 - \eta^2)(1 + \xi \xi_i)}{2} \quad (6)$$

(for mid-side nodes, $i = 4, 8$)

where ξ_i and η_i are the nodal coordinates. $N_i(\xi, \eta) = 1$ at i^{th} node and zero elsewhere and $\sum N_i(\xi, \eta) = 1$. Figure 4 shows the interpolating function for corner and midpoint nodes.

The regional anomalies computed by Equation 3 in the reference element need to be translated to the real survey space. This is carried out as follows:

$$x(\xi, \eta) = \sum M_i(\xi, \eta) x_i \quad (7)$$

$$y(\xi, \eta) = \sum M_i(\xi, \eta) y_i \quad (8)$$

In case of isoparametric element used here, $M_i(\xi, \eta) = N_i(\xi, \eta)$, x_i and y_i are the nodal coordinates shown in Fig. 3a.

A similar methodology holds good for cubic (12 node) as well as irregular (missed node) elements. The appropriate shape functions need to be chosen in each case.

This technique overcomes many of the shortcomings encountered in polynomial fitting, spectral approach, and direct model-based regional computations. Some of these advantages are as follows:

- (i) The observed gravity values only at discrete points, usually the vertices and midpoints of an element superimposing the gravity map, are required for regional computation. The anomalous zones are kept away from the nodal positions.
- (ii) For a quadrilateral ground element in x - y space of any size, shape, and any orientation, the corresponding reference element in ξ - η space is always a square. Therefore, the weighting coefficients needed for the regional computation remain unchanged. The strength of this new technique lies in this property.
- (iii) Only a second-order, or at most a third-order element, approximates the regional field, thereby eliminating the inaccuracies likely to be introduced by fitting very high-order polynomials.
- (iv) The computation is independent of a priori assumptions on the density, form, and depth of shallow or deeper structures.
- (v) The FEM approach is not site-specific, making its application universal.

Accuracy

After a brief description of the finite element concept, the next step consists of testing the accuracy of the computing

Gravity Data, Regional-Residual Separation, Fig. 4

(a) Eight-node quadratic isoparametric element, the shape function, (b) N1 (ξ, η) at a corner node, and (c) N2 (ξ, η) at a mid-side node

technique by comparing the results with those obtained (i) by spectral method for the Paradox Basin (Pawlowski 1994) and (ii) in the space domain for the Klamath Mountains and Cascade Range (Blakely 1995).

Paradox Basin, Utah (Frequency-Domain)

The case study of Pawlowski (1994) for the Paradox Basin, Utah, USA, is considered here because of its elegant approach using a Green's equivalent layer concept to develop a band-pass filter. Secondly, Pawlowski has compared his residual map with that obtained in an earlier study (Hildenbrand and Kucks 1983). In fact, it consists of comparing the FEM regional and residual anomalies with those derived by two independent techniques.

Figure 5 shows a 110 km $\times$ 110 km region of the Bouguer gravity map. Geologically, the Paradox Basin has a large number of NW-SE trending salt domes with hydrocarbon potential. This basin has been studied extensively by different geophysical methods, especially by the gravity method.

Based on the radially averaged Fourier spectrum of the observed gravity field, Pawlowski (1994) related the residual and regional anomalies to two equivalent layers, respectively at 5 km and 54 km depths, and has designed the band-pass filter. By applying this band-pass filter to the observed gravity data, he derived the regional and residual components.

Gravity Data, Regional-Residual Separation, Fig. 5 Bouguer gravity map of Paradox basin, Utah (Pawlowski 1994). Contour interval: 2 mGal

Gravity Data, Regional-Residual Separation, Fig. 6 (a) The regional anomaly obtained by band-pass filtering based on Green's equivalent layer (Pawłowski 1994). Two contour closures present in the map. Contour interval: 2 mGal. (b) The regional gravity anomaly

obtained by FEM approach (12 node). The regional contours trend NW-SE identical with the trends of the deep-seated salt domes. Contour interval: 2 mGal

The regional gravity field obtained by this band-pass filter method is illustrated in Fig. 6a. The regional gravity map shows two contour closures, one on north, and the more prominent one on the southwest corner. These closed contours may indicate the presence of a small portion of the shallower effects. Next, superimposing the 12-node element (nodes are shown in Fig. 2a), the regional component is computed by FEM approach. The resulting regional gravity anomaly is shown in Fig. 6b.

The new regional gravity map does not show any contour closures. The smooth regional contours show NW-SE anomalies identical with the trends of the deep-seated salt domes. In short, FEM regional reflects the deeper structures more faithfully. FEM approach therefore appears to perform better than the band-pass filter technique of Pawłowski (1994).

Residual Gravity Anomalies

In order to get a closer look at the performance of FEM approach to compute the residual anomaly, a 75 km × 75 km window has been taken on the SW corner (see Fig. 6a, b) of the area. Figure 7a, b represent the band-passed and FEM residuals, respectively. A detailed comparison has been made by marking ten anomalous zones A to J in both maps. In each case, the FEM residual appears to be either better or comparable with the corresponding to the residual obtained by spectral technique.

Klamath Mountains and Cascade Range (Model-Based Space-Domain)

To test the accuracy in the space-domain approach, a gravity survey covering parts of Klamath Mountains and Cascade Range in north-central California lying between lat. 40° 52' 30" and 42° N, and long. 121° and 123° W has been considered. In an elegant analysis, Jachens and Griscom (1985) carried out regional-residual separation based on the theory of isostasy and provided an isostatic residual gravity map of this region. Figure 8 shows the isostatic model of Airy-Heiskanen with the following assumptions to compute the regional:

1. A three-layer crust with uniform densities
2. The density of the top layer, $\rho = 2.67 \text{ g/cm}^3$
3. The crustal thickness at sea-level, $T = 25 \text{ km}$, according to a seismic refraction survey
4. The density contrast of the lower layer, $\rho = 0.4 \text{ g/cm}^3$, close to the density contrast, $\rho = 0.385 \text{ g/cm}^3$ (Woollard 1966) based on extensive seismic studies.

In order to account for any deviation in density and crustal thickness from the above parameters, Jachens and Griscom (1985) have taken an upper bound and a lower bound of the regional gravity anomaly by considering two additional sets

Gravity Data, Regional-Residual Separation, Fig. 7 (a) The residual gravity map (Pawlowski 1994) for 75 km $\times$ 75 km survey space. The anomalous zones are shown from A to J. Zones F, I, and J are not well resolved here. Contour interval: 2 mGal. (b) The residual gravity

anomaly obtained by FEM approach (12 node) for 75 km $\times$ 75 km survey space. The anomalous zones from A to J have also well brought out here. The zones F, I, and J are well resolved and two additional zones, E1 and G1 are observed. Contour interval: 1 mGal

Gravity Data, Regional-Residual Separation, Fig. 8 Isostatic model of north-central California. (After Jachens and Griscom 1985)

of parameters: $\rho = 2.50, 2.85 \text{ g/cm}^3$; $T = 20, 30 \text{ km}$; and $\rho = 0.2, 0.6 \text{ g/cm}^3$. Figure 9 shows an east-west regional gravity profile along 41° N. The response of the standard model with $\rho = 2.67 \text{ g/cm}^3$, $T = 25 \text{ km}$, and $\rho = 0.4 \text{ g/cm}^3$ lies between upper and lower bounds. Additionally, Jachens and Griscom examined the regional anomaly for this region based on the Pratt-Hayford model response with a depth of compensation of 113.7 km. These two regional gravity anomalies did not differ appreciably from each other.

In turn, we have computed the regional of the same region by finite element approximation wherein no such assumptions

regarding *layer densities, crustal thickness, density contrast* are required. The open circles lying between the upper and lower bounds in Fig. 9 represent the FEA regional. Its agreement with the standard regional field is good. The deviations at some places between these two regionals can possibly be attributed to the hypothesis of uniform density over the entire region by Jachens and Griscom (1985).

The model-based (Blakely 1995, Fig. 7.21f) and FEA residual anomalies for Klamath Mountains and Cascade Range region are shown in Fig. 10a, b, respectively. The FEA anomalies shown from A to I appear to be better than or comparable to the corresponding model-based anomalies.

It is of interest to note that to arrive at the layer density ρ , crustal thickness (T), and density contrast ($\Delta\rho$), a considerable amount of geological information need to be collected, a large number of experiments, mostly precise (and expensive) seismic surveys, were mounted and a great deal of analysis made. In terms of time and financial input, these might be considerable. In contrast, simply starting from the Bouguer anomaly compares well with what Jachens and Griscom (1985) have very carefully computed. In many countries across the world, information about the layer density, crustal thickness, and density contrast is not available to precisely compute isostatic residual. In such areas, the FEA residual may provide a quick assessment of the gravity anomaly.

Mountains and Cascade Range. Contour interval: 10 mGal. (After Blakely 1995)

Recent Studies on FEM Applications

The success of finite element method has led many investigators to apply this technique to process the theoretical and field gravity data (Kaftan et al. 2005; Agarwal and Srivastava 2010; Ekinci 2010; Ekinci and Yiğitbaş 2012, 2015). Ekinci and Yiğitbaş (2015) have reported interesting results for synthetic simulation and field application. Figure 11 shows the gravity response of three vertical-sided prisms. First, two shallow bodies produce the residual gravity component, while the gravity response of body 3 was assumed to represent the regional effect. The regional anomalies for this model are derived by (a) second-order polynomial, (b) third-order

polynomial, and (c) FEM, and are shown in Fig. 12. It is seen from the figure that the gravity response of the deeper body (body 3) is interestingly enhanced by the use of FEM (Fig. 12a), whereas the maximum gravity amplitudes could not be located over body 3 by polynomial fitting procedure (Fig. 12b, c). Also, there are no pseudo anomalies present in the FEM regional, whereas they slightly contribute in second-order regional and are prominent in third-order polynomial regional. Figure 13 shows the corresponding residual gravity anomalies. The second- and third-order polynomial residuals (Fig. 13a, b) contain number of pseudo anomalies, making it unsuitable for further interpretation. In contrast, the FEM residual in Fig. 13c is far superior in terms of anomaly pattern

Gravity Data, Regional-Residual Separation, Fig. 11 Gravity response of three vertical-sided prisms (Ekinci and Yiğitbaş 2015)

Gravity Data, Regional-Residual Separation, Fig. 12 Regional gravity anomalies by (a) second-order (Ekinci and Yiğitbaş 2015), (b) third-order polynomial (Ekinci and Yiğitbaş 2015), and (c) FEM procedures (Ekinci and Yiğitbaş 2015)

Gravity Data, Regional-Residual Separation, Fig. 13 Residual gravity anomalies by (a) second-order (Ekinici and Yiğitbaş 2015), (b) third-order polynomial (Ekinici and Yiğitbaş 2015), and (c) FEM procedures (Ekinici and Yiğitbaş 2015)

and amplitude. Therefore, it can be inferred that the synthetic simulation method indicated the superiority of the FEM over the polynomial fitting procedure in computing the regional gravity component.

Summary

The separation of regional and residual components from the observed Bouguer gravity (and magnetic) anomaly has remained a subject of debate over the past six to seven decades. Starting from simple graphical to model-based estimation of regional – both in the space and frequency domains – the expected uniqueness has not been achieved. This is due to human judgment and mathematical as well as

geological assumptions. With this backdrop, a new concept based on finite element theory is described above, that performs as good as or often better than the existing techniques both in the frequency and space domain. This has been demonstrated with three examples. FEA technique is not site-specific and can be universally used.

Gravity Field of the Earth

Christopher Jekeli

Division of Geodetic Science, School of Earth Sciences, Ohio State University, Columbus, OH, USA

Definition and Scope

The gravity field of the Earth is generally understood as the field generated by the masses of the terrestrial body. Actual measurements made on the surface include tidal components due to the sun and moon (and theoretically other planets) and the atmosphere, as well as the centrifugal acceleration due to Earth's rotation. Therefore, geodesists distinguish between terrestrial gravitation (mass attraction of the Earth) and gravity (gravitation plus centrifugal acceleration), where tidal and atmospheric effects are treated as corrections. This entry develops the basic physical concepts of terrestrial gravitation assumed to be generated solely by the subsurface mass density distribution. After an introduction to the Newtonian gravitational potential and its properties, the subsequent sections of the entry discuss the spatial variation of the field, the geophysical interpretation of the low-degree harmonics of the field, and briefly the variation of the field inside the Earth.

Introduction

Historical Notes

A study of Earth's gravitational field is a study of Earth's mass structure, its dynamical influence on satellites, and lately its mass redistribution and transport in time. It is also fundamentally and historically a geodetic study of Earth's shape, described largely (70%) by the surface of the oceans (and their conceptual continuation under the continents). Gravitation is a physical phenomenon so pervasive and incidental that humankind generally has taken it for granted with scarcely a second thought. The Greek philosopher Aristotle (384–322 BC) allowed no more than to assert that gravitation is a natural property of material things that causes them to fall (or rise, in the case of some gases), and the more material, the greater the tendency to do so. It was enough of a self-evident explanation that it was not yet to receive the scrutiny of the scientific method. Almost 2000 years later, Galileo Galilei (1564–1642) finally took up the challenge to understand gravitation through observation and scientific investigation. His experimentally derived law of falling bodies corrected the Aristotelian view and divorced the effect of gravitation from the mass of the falling object – all bodies fall with the same acceleration. This truly monumental contribution to physics was, however, only a local explanation of how bodies behaved under gravitational influence. Johannes Kepler's

(1571–1630) observations of planetary orbits pointed to other types of laws, principally an inverse-square law according to which bodies are attracted by forces that vary with the inverse square of distance. The genius of Isaac Newton (1642–1727) brought it all together in his *Philosophiae Naturalis Principia Mathematica* of 1687 with a single and simple all-embracing law that in one bold stroke explained the dynamics of the entire universe (today there is more to understanding the dynamics of the cosmos, but Newton's law remarkably holds its own). The mass of a body was again an essential aspect, not as a self-attribute as Aristotle had implied but as the source of attraction for other bodies: each material body attracts every other material body according to a very specific rule (Newton's law of gravitation). Newton regretted that he could not explain exactly why mass has this property (as one still yearns to know today within the standard models of particle and quantum theories). Even Albert Einstein (1879–1955) in developing his theory of general relativity (i.e., the theory of gravitation) could only improve on Newton's theory by incorporating and explaining action at a distance (gravitational force acts with the speed of light as a fundamental tenet of the theory). Through the principle of equivalence of inertial and gravitational mass, Einstein explained gravitation as the effect that mass has on the fabric of space-time. But what actually mediates the gravitational effect (or, attraction) still intensely occupies modern physicists and cosmologists.

Gravitation since its early scientific formulation initially belonged to the domain of astronomers, at least as far as the observable universe was concerned. Theory successfully predicted the observed perturbations of planetary orbits and even the location of previously unknown new planets (Neptune's discovery in 1846 based on calculations motivated by observed perturbations in Uranus's orbit was a major triumph for Newton's law). However, it was also discovered that gravitational acceleration varies on Earth's surface, with respect to altitude and latitude. Newton's law of gravitation again provided the backdrop for the variations observed with pendulums. An early achievement for his theory came when he successfully predicted the polar flattening in Earth's shape on the basis of hydrostatic equilibrium, which was confirmed finally (after some controversy) with geodetic measurements of long triangulated arcs in 1736–1737 by Pierre de Maupertuis and Alexis Clairaut. Gravitation thus also played a dominant role in geodesy, the science of determining the size and shape of the Earth, promulgated in large part by the father of modern geodesy, Friedrich R. Helmert (1843–1917) (Helmert 1884).

Knowledge of terrestrial gravitation through the twentieth century was crucial for geodetic determination of a well-defined reference surface (a level surface) for heights and to correct astronomic observations of latitude and longitude for the irregular direction of gravitation (Heiskanen and Veing Meinesz 1958; Molodensky et al. 1962; Heiskanen and Moritz 1967; Torge 1989; Sansò and Rummel 1997; Sansò

and Sideris 2013). Also, geophysicists realized the potential of using gravity measurements to infer subsurface structures that could trap oil and gas deposits (e.g., Heiland 1940; Nettleton 1976; Telford et al. 1990). The Earth sciences increasingly rely on accurate gravimetry and gravitational models to aid in the interpretation of other sensor data. For example, oceanographers need an accurate level surface to infer surface currents from sea surface heights measured by satellite altimetry. Geophysicists analyzing crust deformation from GPS measurements of surface point coordinates must know whether the uplift or subsidence is accompanied by a change in subsurface mass – is it an elastic or a viscoelastic response? Ice sheet mapping (e.g., in Antarctica) using airborne laser altimetry must be accompanied with other sensors, such as gravity meters, that can infer the ice-bedrock interface. Hydrologists and glaciologists can now monitor the regional seasonal and secular changes in water/ice mass as seen by gravitation-mapping satellites as they continually orbit the Earth. In our solar system, planetary probes glean significant geophysical information about their targets from the gravitational effect on their orbits as tracked from Earth.

Other perhaps more utilitarian applications also rely on gravitational information. For example, longer-term precision navigation and guidance in the absence of external references, such as GPS, rely on inertial instruments. These autonomous navigation systems sense only inertial acceleration and require gravitational compensation, since a vehicle follows a path governed by both inertial and gravitational acceleration (Einstein's equivalence principle) (Jekeli 2000).

Although not as prominent nor perhaps as prestigious in modern scientific endeavors, gravimetry at all scales, from point measurements to global surveys, continues to hold a critical, at least desirable place in the quest to answer a plethora of macroscopic inquiries into Earth's systems. For a modern view of the role that knowledge of the Earth's gravity field plays in the Earth sciences, see Plag and Pearlman (2009) and references therein.

Newton's Law of Gravitation

In its original form, Newton's law of gravitation applies only to idealized point masses. It describes the force of attraction, $\mathbf{F}$, experienced by two such solitary masses as being proportional to the product of the masses, m_1 and m_2 ; inversely proportional to the square of the distance, ℓ , between them; and directed along the line joining them, as expressed by the unit vector, $\mathbf{n}$:

$$\mathbf{F} = G \frac{m_1 m_2}{\ell^2} \mathbf{n}. \quad (1)$$

G is Newton's gravitational constant that takes care of the units between the left- and right-hand sides of the equation; it can be determined by experiment and the current accepted value is (CODATA 2018 value, NIST 2019):

$$G = (6.67430 \pm 0.00015) \times 10^{-11} \text{ m}^3/(\text{kg s}^2). \quad (2)$$

The unit vector in Eq. (1) is directed from either point mass to the other, and thus the gravitational force is attractive and applies equally to one mass as the other. Newton's law of gravitation is universal as far as we know, requiring reformulation only in Einstein's more comprehensive theory of general relativity which describes gravitation as a characteristic curvature of the space-time continuum (Newton's formulation assumes instantaneous action and differs significantly from the general relativistic concept only when very large velocities or masses are involved; or, conversely, in applications of extremely high precision).

We can ascribe a gravitational acceleration to the gravitational force, which represents the acceleration that one mass undergoes due to the gravitational attraction of the other. Specifically, from the law of gravitation, we have (for point masses) the gravitational acceleration of m_1 due to the gravitational attraction of m_2 :

$$\mathbf{g} = G \frac{m_2}{\ell^2} \mathbf{n}. \quad (3)$$

The vector $\mathbf{g}$ is independent of the mass, m_1 , of the body being accelerated (which Galileo found by experiment).

By the law of superposition, the gravitational force, or the gravitational acceleration, due to many point masses is the vector sum of the forces or accelerations generated by the individual point masses. Manipulating vectors in this way is certainly feasible, but fortunately a more appropriate concept of gravitation as a scalar field simplifies the treatment of arbitrary mass distributions.

This more modern view of gravitation (adopted by eighteenth and nineteenth century mathematicians, such as Lagrange (1736–1813), Gauss (1777–1855), and Green (1793–1841)) holds that it is a *field* having a gravitational potential, V , defined in terms of the gravitational acceleration, $\mathbf{g}$, that a test particle would undergo in the field according to the equation:

$$\nabla V = \mathbf{g}, \quad (4)$$

where ∇ is the gradient operator (a vector operator). We use here the convention that the potential is always positive. Further elucidation of gravitation as a field grew from Einstein's attempt to incorporate gravitation into his theory of special relativity where no reference frame has particular significance above all others. It was necessary to consider that gravitational force is not a real force (i.e., it is not an applied force, like friction or propulsion) – rather it is known as a kinematic force, that is, one whose action is proportional to the mass on which it acts (like the centrifugal force); see (Martin 1988). Under this precept, the geometry of space is defined intrinsically by the gravitational fields contained therein. We continue with the classical Newtonian potential,

but interpret gravitation as an acceleration different from the acceleration induced by real, applied forces. This becomes especially important when considering the measurement of gravitation (Jekeli 2007).

The gravitational potential, V , is a *scalar* function, and it is derived directly on the basis of Newton's law of gravitation. To make it completely consistent with this law and thus declare it a Newtonian potential, we must impose the following conditions of regularity at infinity:

$$\lim_{\ell \rightarrow \infty} \ell V = Gm \quad \text{and} \quad \lim_{\ell \rightarrow \infty} V = 0, \quad (5)$$

where m is the attracting mass. It easily follows from Eqs. (3, 4, and 5) that the gravitational potential at any point in space due to a point mass is:

$$V(\mathbf{x}) = \frac{Gm(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|}, \quad (6)$$

where $\ell = |\mathbf{x} - \mathbf{x}'|$ is the distance from the mass point, $\mathbf{x}'$, to the evaluation point, $\mathbf{x}$, of the potential. Note that the field of a point mass has a singularity at $\mathbf{x} = \mathbf{x}'$.

Applying the law of superposition, the gravitational potential of many point masses is the sum of the potentials of the individual points. And, for infinitely many points in a closed, bounded region with infinitesimally small masses, dm , the summation changes to an integration:

$$V(\mathbf{x}) = G \int_{\text{mass}} \frac{dm(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|}. \quad (7)$$

Changing variables, $dm(\mathbf{x}') = \rho(\mathbf{x}')dv$, where ρ represents density (mass per volume) and dv is a volume element, we have:

$$V(\mathbf{x}) = G \iiint_v \frac{\rho(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} dv. \quad (8)$$

In spherical polar coordinates, the evaluation and integration points are (θ, λ, r) and (θ', λ', r') , respectively. The volume element in this case is given by $dv = r'^2 \sin \theta' d\lambda' d\theta' dr'$. It is readily shown that if the evaluation point, $\mathbf{x}$, is inside the volume, v , then by placing the coordinate origin at $\mathbf{x}$, one has $dv = |\mathbf{x}'|^2 \sin \theta' d\lambda' d\theta' dr'$, and the apparent singularity disappears – the integral is said to be weakly singular. Indeed, the potential of a volume of mass density is continuous and differentiable everywhere.

Suppose the density distribution over the volume depends only on radial distance (from the center of mass, assumed to be at the origin): $\rho = \rho(r')$, and that the evaluation is at an exterior point. The surface bounding the masses necessarily is

a sphere (say, of radius, R) and with an appropriate choice of coordinates, one easily shows (e.g., Jekeli 2007) that the integral (8) becomes:

$$V(\theta, \lambda, r) = \frac{GM}{r}, \quad r \geq R, \quad (9)$$

where M is the total mass bounded by the sphere. To a reasonably good approximation, Earth's density structure is spherically symmetric (see section “[Low-Degree Harmonics as Density Moments](#)”), and the external gravitational potential is that of a point mass (the approximation is valid to one part in 2000).

Besides volumetric mass (density) distributions, it is of interest to consider surface distributions. Imagine an infinitesimally thin layer of mass on a surface, s , where the units of density in this case are those of mass per area. Then, analogous to Eq. (8), the potential is:

$$V(\mathbf{x}) = G \iint_s \frac{\kappa(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} ds, \quad (10)$$

where κ is the surface mass density. In this case, V is a continuous function everywhere, but its first derivatives are discontinuous at the surface.

Now, imagine two infinitesimally close density layers (double layer or layer of mass dipoles), where the units of density are those of mass per area times length. The potential in this case is given by (see Heiskanen and Moritz 1967, p. 8):

$$V(\mathbf{x}) = G \iint_s \kappa(\mathbf{x}') \frac{\partial}{\partial n} \left(\frac{1}{|\mathbf{x} - \mathbf{x}'|} \right) ds, \quad (11)$$

where $\partial/\partial n$ is the directional derivative along the perpendicular to the surface. Now, V itself is discontinuous at the surface, as are all its derivatives. In all cases, V is a Newtonian potential, having been derived from the basic formula (6) for a point mass that follows from Newton's law of gravitation, Eq. (1).

The following properties of the gravitational potential are useful and foundational for many applications. First, consider Stokes's theorem, for a vector function, $\mathbf{f}$, defined on a surface, s :

$$\iint_s (\nabla \times \mathbf{f}) \cdot \mathbf{n} ds = \oint_p \mathbf{f} \cdot d\mathbf{r}, \quad (12)$$

where p is any closed path in the surface, $\mathbf{n}$ is the unit vector perpendicular to the surface, and $d\mathbf{r}$ is a differential displacement along the path. From Eq. (4), we find:

$$\nabla \times \mathbf{g} = \mathbf{0}, \quad (13)$$

since $\nabla \times \nabla = \mathbf{0}$, and hence, applying Stokes's theorem, we find with $\mathbf{f} = m\mathbf{g}$ that:

$$w = \oint_p m\mathbf{g} \cdot d\mathbf{r} = 0. \quad (14)$$

That is, the gravitational field is conservative: the work, w , expended in moving a mass around a closed path in this field vanishes. In contrast, dissipating forces (real forces!), like friction, expend work or energy, which shows again the special nature of the gravitational force.

It can be shown (Kellogg 1953, p.156) that the second partial derivatives of a Newtonian potential, V , satisfy the following differential equation, known as Poisson's equation:

$$\nabla^2 V = -4\pi G\rho, \quad (15)$$

where $\nabla^2 = \nabla \cdot \nabla$ formally is the scalar product of two gradient operators and is called the Laplacian operator. In Cartesian coordinates, it is given by:

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}. \quad (16)$$

Equation (15) is a local characterization of the potential field, as opposed to the global characterization given by Eq. (8). Poisson's equation holds wherever the mass density, ρ , satisfies certain conditions similar to continuity (Hölder conditions, see Kellogg 1953, pp.152–153). A special case of Eq. (15) applies for those points where the density vanishes (i.e., in free space); then Poisson's equation turns into Laplace's equation:

$$\nabla^2 V = 0. \quad (17)$$

It is easily verified that the point mass potential satisfies Eq. (17); that is,

$$\nabla^2 \left(\frac{1}{|\mathbf{x} - \mathbf{x}'|} \right) = 0, \quad \mathbf{x} \neq \mathbf{x}'. \quad (18)$$

The solutions to Laplace's Eq. (17) are known as harmonic functions (here, we also impose the conditions (5) on the solution, if it is a Newtonian potential and if the mass-free region includes infinity). Hence, every Newtonian potential is a harmonic function in free space. The converse is also true: every harmonic function can be represented as a Newtonian potential of a mass distribution.

Several structures of the Earth's crust may be approximated by forms characterized essentially by a two-

dimensional cross-section, such as sheets, slabs, dikes, and faults, that extend indefinitely in one dimension. The gravitational potential associated with such density contrasts is known as a logarithmic potential, since the potential (up to an arbitrary constant) of an infinite, straight line (that is, a differential element of the cross-section) is given by (Telford et al. 1990; Kellogg 1953):

$$\delta V(\mathbf{x}) = 2G\mu \ln \frac{1}{r}, \quad (19)$$

where r is the distance of the evaluation point, $\mathbf{x}$, from the line and μ is the constant linear mass density of the line. If the line is indefinitely extended in the y -direction, then the potential of any form with cross A in the x - z plane is:

$$V(\mathbf{x}) = 2G\mu \iint_A \ln \frac{1}{\sqrt{(x-x')^2 + (z-z')^2}} dx' dz'. \quad (20)$$

Strictly speaking, the logarithmic potential is not a Newtonian potential since it does not vanish when $r \rightarrow \infty$ (on account of the arbitrary constant); however, it is a useful approximation in many geophysical applications.

Spatial and Temporal Variation Above the Surface

This section develops two types of solutions to standard boundary-value problems when the boundary is a sphere: the spherical harmonic series and an integral with a Green's function. Attention is given to the Dirichlet boundary-value problem for the exterior region (that includes infinity). That is, the gravitational potential, V , satisfies Laplace's Eq. (17) everywhere outside the sphere, and the solution to this partial differential equation is sought based on values of V given on the sphere. Other types of boundary-value problems presume given linear combinations of zero- and first-order derivatives of the potential on the boundary. Also, other boundaries that better approximate the Earth yield more difficult solutions – the ellipsoid is relatively easy (Hotine 1969; Jekeli 1988), whereas, the Earth's surface is challenging (Molodensky et al. 1962; Moritz 1980). With the spherical boundary, one obtains a particularly straightforward spectral representation that allows analysis of the spatial variation of the field at different wavelengths.

Spherical Harmonics

For simple boundaries, Laplace's Eq. (17) is relatively easy to solve provided there is an appropriate coordinate system. For the Earth, the solutions commonly rely on approximating the boundary by a sphere of radius, R . In spherical polar coordinates, (θ, λ, r) , the Laplacian operator is given by:

$$\nabla^2 = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) + \frac{1}{r^2} \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2}{\partial \lambda^2}, \quad (21)$$

and solutions to $\nabla^2 V = 0$ in the space outside a sphere of radius, R , with center at the coordinate origin are (Kellogg 1953, p. 143; Morse and Feshbach 1953, p. 1264; Hobson 1965, p. 10):

$$V(\theta, \lambda, r) = P_{nm}(\cos \theta) \sin m\lambda \frac{1}{r^{n+1}} \quad \text{and} \quad V(\theta, \lambda, r) = P_{nm}(\cos \theta) \cos m\lambda \frac{1}{r^{n+1}}, \quad (22)$$

where $P_{nm}(y)$ is the associated Legendre function of the first kind and n, m are integers such that $0 \leq m \leq n, n \geq 0$. Other solutions exist, but only Eqs. (22) are consistent with the problem of finding a real-valued Newtonian potential for the exterior space of the Earth (regular at infinity and 2π -periodic in longitude).

The general solution is a linear combination of solutions (22) for all possible integers, n and m ,

$$V(\theta, \lambda, r) = \sum_{n=0}^{\infty} \sum_{m=-n}^n \left(\frac{R}{r} \right)^{n+1} v_{nm} \bar{Y}_{nm}(\theta, \lambda), \quad (23)$$

where the $\bar{Y}_{nm}$ are surface spherical harmonic functions defined as:

$$\bar{Y}_{nm}(\theta, \lambda) = \bar{P}_{n|m|}(\cos \theta) \begin{cases} \cos m\lambda, & m \geq 0 \\ \sin |m|\lambda, & m < 0 \end{cases} \quad (24)$$

and $\bar{P}_{nm}$ is a normalization of P_{nm} so that the orthogonality of the spherical harmonics is:

$$\frac{1}{4\pi} \iint_{\sigma} \bar{Y}_{nm}(\theta, \lambda) \bar{Y}_{n'm'}(\theta, \lambda) d\sigma = \begin{cases} 1, & n = n' \text{ and } m = m' \\ 0, & n \neq n' \text{ or } m \neq m' \end{cases} \quad (25)$$

where $\sigma = \{(\theta, \lambda) | 0 \leq \theta \leq \pi, 0 \leq \lambda \leq 2\pi\}$ represents the unit sphere, with $d\sigma = \sin \theta d\theta d\lambda$. For a complete mathematical treatment of spherical harmonics, see Müller (1966). The functions, $\bar{Y}_{nm}(\theta, \lambda)/r^{n+1}$, are also known as solid spherical harmonics.

The constant coefficients, v_{nm} , known as Stokes's constants, have identical units of measure. Applying the orthogonality relation, Eq. (25), to the general solution (23), these coefficients can be determined if the function, V , is known on the bounding sphere (Dirichlet boundary condition):

$$v_{nm} = \frac{1}{4\pi} \int_{\sigma} V(\theta, \lambda, R) \bar{Y}_{nm}(\theta, \lambda) d\sigma. \quad (26)$$

The spherical harmonic expansion of V , Eq. (23), with Eq. (26) for the coefficients is a solution to the Dirichlet boundary-value problem if the boundary is a sphere. The solution thus exists and is unique in the sense that these boundary values generate no other potential.

In a more formal mathematical setting, the solution (23) is an infinite linear combination of orthogonal basis functions (eigenfunctions) and the coefficients, v_{nm} , are the corresponding eigenvalues. One may also interpret the set of coefficients as the spectrum (Fourier-Legendre spectrum) of the potential on the sphere of radius, R (analogous to the Fourier spectrum of a function depending on Cartesian coordinates on the plane or line). The integers, n, m , correspond to wavenumbers and are called degree (n) and order (m), respectively.

The spherical harmonics are further classified as zonal ($m = 0$), meaning that the zeros of $\bar{Y}_{n0}$ divide the sphere into latitudinal zones; sectorial ($|m| = n$), where the zeros of $\bar{Y}_{nm}$ divide the sphere into longitudinal sectors; and tesseral ($0 < |m| < n$), where the zeros of $\bar{Y}_{nm}$ tessellate the sphere (Fig. 1).

Recent global mappings of the Earth's gravitational field using satellite observations, specifically the GRACE mission (Gravity Recovery and Climate Experiment, Tapley et al. 2004), have emphasized the temporal dependence of the potential due to mass transport on and within the Earth (hydrologic flux, glacial isostatic adjustment, ice mass loss). In terms of the global spherical harmonic expansion, this implies a temporal dependence in the Stokes's coefficients:

$$V(\theta, \lambda, r; t) = \sum_{n=0}^{\infty} \sum_{m=-n}^n \left(\frac{R}{r} \right)^{n+1} v_{nm}(t) \bar{Y}_{nm}(\theta, \lambda). \quad (27)$$

While the spherical harmonic series has its advantages in global representations and spectral interpretations of the field, the support region for each of its basis functions is global, which can be inefficient from the standpoint of data analysis. As more data are incorporated, or improved, each coefficient, v_{nm} , must be reestimated. Representations using local-support basis functions have recently been developed (e.g., Freedman et al. 1998) and are topics of current research. Such constructions also permit multi-resolution decompositions analogous to wavelet analysis.

Green's Functions

The Green's function representation of the field also offers a more regional characterization of the field. Although the Green's function strictly has global support, it attenuates rapidly from the evaluation point of the potential and reflects that a remote change in boundary value generally does not appreciably affect the local determination of the field.

Gravity Field of the Earth, Fig. 1 Spherical harmonics of the types zonal (left), sectorial (middle), and tesseral (right)

When the boundary is a sphere, the solution to the boundary-value problem using a Green's function is easily derived for the potential from its spherical harmonic series representation. Additional integral relationships (with appropriate Green's functions) among all the derivatives of the potential can be derived similarly (Jekeli 2007). Using the decomposition formula for the n^{th} -degree Legendre polynomial,

$$P_n(\cos \psi) = \frac{1}{2n+1} \sum_{m=-n}^n \bar{Y}_{nm}(\theta, \lambda) \bar{Y}_{nm}(\theta', \lambda'), \quad (28)$$

where

$$\cos \psi = \cos \theta \cos \theta' + \sin \theta \sin \theta' \cos(\lambda - \lambda'), \quad (29)$$

and substituting the harmonic coefficients, Eq. (26), into the series, Eq. (23), we find:

$$V(\theta, \lambda, r) = \frac{1}{4\pi} \iint_{\sigma} V(\theta', \lambda', R) U(\psi, r) d\sigma, \quad (30)$$

where with $\ell = \sqrt{r^2 + R^2 - 2rR \cos \psi}$

$$\begin{aligned} U(\psi, r) &= \sum_{n=0}^{\infty} (2n+1) \left(\frac{R}{r}\right)^{n+1} P_n(\cos \psi) \\ &= \frac{R(r^2 - R^2)}{\ell^3}. \end{aligned} \quad (31)$$

The closed formula (right side of Eq. (31)) comes from an appropriate manipulation of the Coulomb expansion (Cushing 1975, p. 155) for the reciprocal distance,

$$\frac{1}{\ell} = \frac{1}{R} \sum_{n=0}^{\infty} \left(\frac{R}{r}\right)^{n+1} P_n(\cos \psi). \quad (32)$$

Solutions (23) and (30) to the Dirichlet boundary-value problem for a spherical boundary are identical. The integral,

Eq. (30), is known as the Poisson integral and the function U is also known as Poisson's kernel.

The Disturbing Potential

For convenience, one separates Earth's gravitational potential into a reference potential (section "Normal Reference Field") and the disturbing potential, T . The disturbing potential is harmonic in free space, satisfies Poisson's integral if the boundary is a sphere, and is expandable in a series of solid spherical harmonics:

$$\begin{aligned} T(\theta, \lambda, r) &= \frac{GM}{R} \sum_{n=0}^{\infty} \\ &\times \sum_{m=-n}^n \left(\frac{R}{r}\right)^{n+1} \delta C_{nm} \bar{Y}_{nm}(\theta, \lambda) \end{aligned} \quad (33)$$

where M is the total mass (including the atmosphere) of the Earth and the δC_{nm} are unitless harmonic coefficients, being also the difference between coefficients for the total and reference gravitational potentials. The coefficient, δC_{00} , is zero under the assumption that the reference field accounts completely for the central part of the total field. Note that also these coefficients specifically refer to the sphere of radius, R .

The gravity anomaly (in spherical approximation) is defined by:

$$\Delta g(\theta, \lambda, r) = \left(-\frac{\partial}{\partial r} - \frac{2}{r}\right) T(\theta, \lambda, r), \quad (34)$$

or, using Eq. (33),

$$\begin{aligned} \Delta g(\theta, \lambda, r) &= \frac{GM}{R^2} \sum_{n=0}^{\infty} \\ &\times \sum_{m=-n}^n \left(\frac{R}{r}\right)^{n+2} (n-1) \delta C_{nm} \bar{Y}_{nm}(\theta, \lambda). \end{aligned} \quad (35)$$

The spectral relationship for $n \geq 2$ between gravity anomalies and the disturbing potential, obtained by comparing Eqs. (33 and 35), leads to a corresponding Green's function

that transforms one to the other. This function in geodesy is called more commonly Stokes's function:

$$S(\psi, r) = \sum_{n=2}^{\infty} \frac{2n+1}{n-1} \left(\frac{R}{r}\right)^{n+1} P_n(\cos \psi) \\ = 2\frac{R}{\ell} + \frac{R}{r} - 3\frac{R\ell}{r^2} - 5\frac{R^2}{r^2} \cos \psi - 3\frac{R^2}{r^2} \cos \psi \ln \frac{\ell + r - R \cos \psi}{2r} \quad (36)$$

and thus, without zero and first-degree harmonics (Hofmann-Wellenhof and Moritz 2005; Jekeli 2007):

$$T(\theta, \lambda, r) = \frac{R}{4\pi} \iint_{\sigma} \Delta g(\theta', \lambda', R) S(\psi, r) d\sigma, \quad (37)$$

which is known as the Pizzetti-Stokes integral. This equation in geodesy solves the Robin boundary-value problem for the sphere: the potential and its normal derivative are given on the boundary; see Eq. (34).

The solution is not unique since, as Eq. (35) shows, the gravity anomaly has no first-degree harmonics, which, therefore, cannot be determined from the boundary values. Conventionally, as shown in Eq. (36), the Stokes kernel also excludes the zero-degree harmonic and thus the complete solution for the disturbing potential is given by:

$$T(\theta, \lambda, r) = \frac{GM}{r} \delta C_{00} + \frac{GM}{R} \\ \times \sum_{m=-1}^1 \left(\frac{R}{r}\right)^2 \delta C_{1m} \bar{Y}_{1m}(\theta, \lambda) \\ + \frac{R}{4\pi} \iint_{\sigma} \Delta g(\theta', \lambda', R) S(\psi, r) d\sigma. \quad (38)$$

The central term, δC_{00} , is proportional to the difference in GM of the Earth and reference ellipsoid and is zero to high accuracy. The first-degree harmonic coefficients, δC_{1m} , are proportional to the center-of-mass coordinates and can also be set to zero with appropriate definition of the coordinate system (section “Low-Degree Harmonics as Density Moments”). Thus, the Pizzetti-Stokes integral (37) is the more common expression for the disturbing potential, but it embodies hidden constraints.

Spectral Contributions

The correlation function of the disturbing potential on a sphere is defined as (Moritz 1980; Jekeli 2017):

$$\phi_T(\psi) = \frac{1}{8\pi^2} \int_0^{2\pi} \int_0^{2\pi} \int_{\sigma} T(\theta, \lambda, R) T(\theta', \lambda', R) \sin \theta d\theta d\lambda d\alpha, \quad (39)$$

where the points (θ, λ, R) and (θ', λ', R) are connected by Eq. (29) and their relative azimuth, α ,

$$\tan \alpha = \frac{-\sin \theta' \sin(\lambda - \lambda')}{\sin \theta \cos \theta' - \cos \theta \sin \theta' \cos(\lambda - \lambda')}, \quad (40)$$

and where the integration is performed over all possible pairs of these points, with fixed spherical distance, ψ , $0 \leq \psi \leq \pi$.

Because of its sole dependence on ψ , ϕ_T can be expressed as an infinite series of Legendre polynomials:

$$\phi_T(\psi) = \sum_{n=0}^{\infty} (2n+1) (\Phi_T)_n P_n(\cos \psi). \quad (41)$$

where the coefficients, $(\Phi_T)_n$, constitute the Legendre transform of ϕ_T :

$$(\Phi_T)_n = \frac{1}{2} \int_0^{\pi} \phi_T(\psi) P_n(\cos \psi) \sin \psi d\psi. \quad (42)$$

Substituting Eqs. (28) and (39) into Eq. (42), and then simplifying using the orthogonality of spherical harmonics, Eq. (25), and the definition of the Fourier-Legendre spectrum, Eq. (26), we find:

$$(\Phi_T)_n = \frac{1}{2n+1} \sum_{m=-n}^n v_{nm}^2. \quad (43)$$

The quantities, $(\Phi_T)_n$, constitute the power spectral density (PSD) of T , and

$$(c_T)_n = (2n+1) (\Phi_T)_n \quad (44)$$

is known as a degree variance or variance per degree, since the total variance, from Eq. (41), is:

$$\phi_T(0) = \sum_{n=0}^{\infty} (c_T)_n. \quad (45)$$

For the first and second radial derivatives of the disturbing potential, called the gravity disturbance ($\delta g = -\partial T / \partial r$) and vertical-vertical gradient disturbance ($\delta \Gamma = \partial^2 T / \partial r^2$), one has analogous PSDs that are related to the PSD of T as follows:

$$(\Phi_{\delta \Gamma})_n = \left(\frac{n+2}{R}\right)^2 (\Phi_{\delta g})_n \\ = \left(\frac{n+2}{R}\right)^2 \left(\frac{n+1}{R}\right)^2 (\Phi_T)_n. \quad (46)$$

Using one of the more recent high-degree Earth Gravitational Models, EGM2008 (Pavlis et al. 2012), Fig. 2

Gravity Field of the Earth,

Fig. 2 Degree variances of radial derivatives of the Earth's disturbing potential. All values are normalized by the respective total variance

illustrates the relative spectral content of the derivatives of the (disturbing) gravitational potential. Clearly, the higher derivatives emphasize the shorter wavelengths (or higher degrees, higher frequencies). The EGM2008 model has maximum degree 2160, corresponding to about 9.3 km resolution on the Earth's surface ($180^\circ/2160 = 5$ arcmin).

Low-Degree Harmonics

The low-degree spherical harmonics of the Earth's gravitational potential lend themselves to interpretation with respect to the most elemental distribution of the Earth's mass density, which also leads to fundamental geometric characterizations, particularly for the second-degree harmonics. Let

$$C_{nm}^{(a)} = \frac{a}{GM} \left(\frac{R}{a}\right)^{n+1} v_{nm} \quad (47)$$

be unitless coefficients that refer to a sphere of radius, a , which is the equatorial radius of the Earth ellipsoid. (Recall that coefficients, v_{nm} , Eq. (50), refer to a sphere of radius, R .) Relative to the central harmonic coefficient, $C_{00}^{(a)} = 1$, the next significant harmonic, $C_{20}^{(a)}$, is more than three orders of magnitude smaller, and the remaining harmonic coefficients are at least two to three orders of magnitude smaller than that. The attenuation of the coefficients after degree two is much more gradual (Table 1, below), indicating that the bulk of the potential can be described by an ellipsoidal field. The normal gravitational field is such a field, but it also adheres to a geodetic definition that requires the underlying ellipsoid to be an equipotential surface in the corresponding normal gravity field. The following sections examine the low-degree harmonics from these two perspectives of interpretation and reference.

Low-Degree Harmonics as Density Moments

Returning to the general expression for the gravitational potential in terms of the Newtonian density integral (Eq. (8)) and substituting the spherical harmonic series for the reciprocal distance (Eq. (32) with (28)):

$$V(\theta, \lambda, r) = \sum_{n=0}^{\infty} \sum_{m=-n}^n \left(\frac{R}{r}\right)^{n+1} \left(\frac{G}{R^{n+1}(2n+1)} \iiint_V (r')^n \bar{Y}_{nm}(\theta', \lambda') \rho(\theta', \lambda', r') dv \right) \bar{Y}_{nm}(\theta, \lambda) \quad (48)$$

yields a multipole expansion (so-called from electrostatics) of the potential. The spherical harmonic (Stokes) coefficients are multipoles of the density distribution:

$$v_{nm} = \frac{G}{R^{n+1}(2n+1)} \iiint_V (r')^n \bar{Y}_{nm}(\theta', \lambda') \rho(\theta', \lambda', r') dv. \quad (49)$$

One may also consider the n th-order moments of the mass density (from the statistics of distributions) defined by:

$$\begin{aligned} \mu_{\alpha\beta\gamma}^{(n)} &= \iiint_V (x')^\alpha (y')^\beta (z')^\gamma \rho dv, \\ n &= \alpha + \beta + \gamma. \end{aligned} \quad (50)$$

The multipoles of degree n and the moments of order n are related, though not all $(n+1)(n+2)/2$ moments of order n can be determined from the $2n+1$ multipoles of degree n , when $n \geq 2$ (clearly risking confusion, we defer to the common nomenclature of “order” for moments and “degree” for multipoles). This indeterminacy is directly connected to the inability to determine the density distribution uniquely from external measurements of the potential (Chao 2005), which is a characteristic of the classic geophysical inverse problem.

The zero-degree Stokes coefficient is coordinate invariant and is proportional to the total mass of the Earth:

$$v_{00} = \frac{G}{R} \iiint_V \rho dv = \frac{GM}{R}. \quad (51)$$

It also represents a mass monopole, and it is proportional to the zeroth moment of the density.

The first-degree harmonic coefficients (representing dipoles) are proportional to the coordinates of the center of mass, (x_{cm}, y_{cm}, z_{cm}) , which are proportional to the first-order moments of the density, as verified by recalling the definition of the first-degree spherical harmonics:

$$\begin{aligned} v_{1m} &= \frac{G}{\sqrt{3}R^2} \iiint_V \rho \begin{cases} r' \sin \theta' \sin \lambda', & m = -1 \\ r' \cos \theta', & m = 0 \\ r' \sin \theta' \cos \lambda', & m = 1 \end{cases} dv \\ &= \frac{GM}{\sqrt{3}R^2} \begin{cases} y_{cm}, & m = -1 \\ z_{cm}, & m = 0 \\ x_{cm}, & m = 1 \end{cases} \end{aligned} \quad (52)$$

Nowadays, by tracking satellites, we have access to the center of mass of the Earth (including its atmosphere) since it defines the “center” of their orbits. Ignoring the small motion of the center of mass (annual amplitude of several mm) due to the

temporal variations in the mass distribution, we may choose the coordinate origin for the gravitational potential to coincide with the center of mass, thus essentially annihilating the first-degree coefficients.

The second-order density moments likewise are related to the second-degree harmonic coefficients (quadrupoles). They also define the inertia tensor of the body. The inertia tensor is the proportionality factor in the equation that relates the angular momentum vector, $\mathbf{H}$, and the angular velocity, $\boldsymbol{\omega}$, of a body, like the Earth:

$$\mathbf{H} = \mathbf{I}\boldsymbol{\omega}, \quad (53)$$

and is given by:

$$\mathbf{I} = \begin{pmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{pmatrix}. \quad (54)$$

It comprises the moments of inertia on the diagonal:

$$\begin{aligned} I_{xx} &= \iiint_{\text{volume}} (y'^2 + z'^2) \rho dv, \\ I_{yy} &= \iiint_{\text{volume}} (z'^2 + x'^2) \rho dv, \\ I_{zz} &= \iiint_{\text{volume}} (x'^2 + y'^2) \rho dv, \end{aligned} \quad (55)$$

and the products of inertia off the diagonal:

$$\begin{aligned} I_{xy} &= I_{yx} = - \iiint_{\text{volume}} x' y' \rho dv, \\ I_{xz} &= I_{zx} = - \iiint_{\text{volume}} x' z' \rho dv, \\ I_{yz} &= I_{zy} = - \iiint_{\text{volume}} y' z' \rho dv. \end{aligned} \quad (56)$$

Note that:

$$\begin{aligned} I_{xx} &= \mu_{020}^{(2)} + \mu_{002}^{(2)}, & I_{xy} &= -\mu_{110}^{(2)}, & I_{xz} &= -\mu_{101}^{(2)} \\ I_{yy} &= \mu_{002}^{(2)} + \mu_{200}^{(2)}, & I_{yz} &= -\mu_{011}^{(2)} \\ I_{zz} &= \mu_{200}^{(2)} + \mu_{020}^{(2)} \end{aligned} \quad (57)$$

and there as many (6) independent tensor components as second-order density moments. Using the explicit expressions for the second-degree spherical harmonics, we have from Eq. (49) with $n = 2$:

$$\begin{aligned}
v_{2,-2} &= -\frac{\sqrt{15}}{5R^3} G I_{xy}, & v_{2,-1} &= -\frac{\sqrt{15}}{5R^3} G I_{yz}, \\
v_{2,1} &= -\frac{\sqrt{15}}{5R^3} G I_{xz}, & v_{2,0} &= \frac{\sqrt{5}}{10R^3} G (I_{xx} + I_{yy} - 2I_{zz}), \\
v_{2,2} &= \frac{\sqrt{15}}{10R^3} G (I_{yy} - I_{xx})
\end{aligned} \tag{58}$$

These are also known as MacCullagh's formulas. Not all density moments (or moments of inertia) can be determined from the Stokes coefficients.

If the coordinate axes are chosen so as to diagonalize the inertia tensor (products of inertia are equal to zero), then they are known as principal axes of inertia, or also "figure" axes. For the Earth, the z -figure axis is very close to the spin axis (within several meters at the pole); both axes move with respect to each other and with respect to the Earth's crust, with combinations of various periods (daily, monthly, annual, etc.), as well as secularly in a wandering fashion. Because of these polar motions, the figure axis is not a useful coordinate axis that defines a frame fixed to the (surface of the) Earth. However, because of the proximity of the figure axis to the defined reference z -axis, the second-degree, first-order harmonic coefficients of the geopotential, and hence the products of inertia, I_{xz} and I_{yz} , are relatively small (Table 1).

The arbitrary choice of the x -axis of our Earth-fixed reference coordinate system certainly did not attempt to eliminate the product of inertia, I_{xy} (the x -axis is defined by the intersection of the Greenwich meridian with the equator, and the y -axis completes a right-handed mutually orthogonal triad). However, it is possible to determine where the x -figure axis is located by combining values of the second-degree, second-order harmonic coefficients. Let u, v, w be the axes that define a coordinate system in which the inertia tensor is diagonal, and assume that the approximation, $I_{ww} = I_{zz}$, holds. A rotation by the angle, $-\lambda_0$, about the w - (also z -) figure axis brings this ideal coordinate system back to the conventional one in which we calculate the harmonic coefficients from satellite tracking data. Tensors transform under rotation, defined by matrix, $\mathcal{R}$, according to:

$$I_{xyz} = \mathcal{R} I_{uvw} \mathcal{R}^T. \tag{59}$$

With the rotation about the w -axis given by the matrix:

$$\mathcal{R} = \begin{pmatrix} \cos \lambda_0 & -\sin \lambda_0 & 0 \\ \sin \lambda_0 & \cos \lambda_0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{60}$$

and with Eqs. (58), it is straightforward to show that:

$$\begin{aligned}
v_{2,-2} &= -\frac{\sqrt{15}G}{10R^3} (I_{uu} - I_{vv}) \sin 2\lambda_0 \\
v_{2,2} &= -\frac{\sqrt{15}G}{10R^3} (I_{uu} - I_{vv}) \cos 2\lambda_0
\end{aligned} \tag{61}$$

Hence, we have:

$$\lambda_0 = \frac{1}{2} \tan^{-1} \frac{v_{2,-2}}{v_{2,2}}, \tag{62}$$

where the quadrant is determined by the signs of the harmonic coefficients. From Table 1 and Eq. (47), we find that $\lambda_0 = -14.929^\circ$, i.e., the u -figure axis is in the mid-Atlantic between South America and Africa.

The second-degree, second-order harmonic coefficient, $v_{2,2}$, indicates the asymmetry of the Earth's mass distribution projected on the equator. Since $v_{2,2} > 0$ (for the Earth), Eqs. (61) show that $I_{vv} > I_{uu}$ and thus the equator "bulges" more in the direction of the u -figure axis; conversely, the equator is flattened in the direction of the v -figure axis. This flattening is relatively small: $1.1 \cdot 10^{-5}$.

Finally, consider the most important second-degree harmonic coefficient, the second zonal harmonic, $v_{2,0}$. Irrespective of the x -axis definition, it is proportional to the difference between the moment of inertia, I_{zz} , and the average of the equatorial moments, $(I_{xx} + I_{yy})/2$. Again, since $v_{2,0} < 0$, the Earth bulges more around the equator and is flattened at the poles. The second zonal harmonic coefficient is roughly 1000 times larger than the other second-degree coefficients and thus indicates a substantial polar flattening (owing to the Earth's early more fluid state). This flattening is approximately 0.003.

Normal Reference Field

A model for the Earth's gravitational field that is mathematically simple and yet accurate to better than one part in 63,000 (for the potential) is based on an ellipsoid of revolution rather than the sphere. The precise geodetic definition of the normal (reference) gravitational potential is that it is generated by an ellipsoidal mass that rotates with the Earth such that the gravitational potential plus the "centrifugal potential" due to the centrifugal acceleration (related as in Eq. (4)) is a constant, U_0 , on the ellipsoid. This definition sets up a Dirichlet boundary-value problem, whose solution is an analytic expression in ellipsoidal coordinates (Hofmann-Wellenhof and Moritz 2005). The boundary is defined by two parameters, the semi-major axis, a , and polar flattening, f , of the (rotationally symmetric) normal ellipsoid; the boundary values of the potential are defined by the given constant, U_0 , and the rotation rate of the Earth, ω_e (which specifies the centrifugal potential at any particular latitude). The normal ellipsoid, by definition, is centered at Earth's center of mass.

The solution for the normal potential is thus based on four fundamental constants, Earth's rotation rate, the size and shape parameters of the ellipsoid, and a gravitational scale parameter. The constant, U_0 , is related to several other gravitational quantities, such as the value of normal gravity (mass attraction plus the centrifugal acceleration) at the equator, or the total mass of the ellipsoid, or it could simply be taken as the potential value of the geoid. It can be shown (Hofmann-Wellenhof and Moritz 2005) that:

$$U_0 = \frac{GM}{E} \tan^{-1} \frac{E}{b} + \frac{1}{3} \omega_e^2 a^2, \quad (63)$$

where $b = a(1 - f)$ is the semi-minor axis, $E = \sqrt{a^2 - b^2}$ is the linear eccentricity of the ellipsoid, and M is its total mass. The mass density is not constant within the normal ellipsoid and its variation does not approximate Earth's internal structure. Rather the normal gravity potential (the sum of gravitational potential due to mass attraction and the centrifugal potential) is designed to emulate the actual external field, being constant on the ellipsoid, just as the actual gravity potential is constant on the geoid.

The normal field is always defined by adopting values of the four parameters that approximately match the corresponding actual parameters for the Earth. Before artificial Earth-orbiting satellites, the gravitational scale could best be accessed by measuring gravity (e.g., a nominal value at the equator served as the physical scale parameter). By tracking satellites, the value of GM for the Earth (total mass including the atmosphere) can be estimated to high accuracy and is still used today to define the physical scale of the normal potential. The ellipsoid parameters were traditionally determined from (partially) global geometric surveying networks projected onto a best-fitting ellipsoid. Today, the semi-major axis is well determined from a best fit of an ellipsoid to a global set of ocean heights derived from satellite altimeter data. The polar flattening, according to the section “Low-Degree Harmonics as Density Moments,” is related to the second zonal harmonic of Earth's gravitational potential, which likewise can be estimated very accurately from satellite tracking data. The second zonal harmonic coefficient, the *dynamical form factor*, thus serves as the shape parameter for the normal

ellipsoid. Table 2 lists internationally adopted normal ellipsoids over the past 100 years.

The exact analytical expression for the normal gravity potential then yields exact expressions for the normal gravity (and gravitation) and all its gradients. Nevertheless, approximate series expressions are sometimes preferred, especially to conform to a particular coordinate system. For example, the normal gravitational potential (due only to mass attraction) in spherical polar coordinates is given by:

$$V(\theta, \lambda, r) = \frac{GM}{r} \left(1 - \sum_{n=2}^{\infty} J_{2n} \left(\frac{a}{r} \right)^{2n} P_{2n}(\cos \theta) \right), \quad (64)$$

where with $e = E/a$ (the first eccentricity),

$$J_{2n} = (-1)^{n+1} \frac{3e^{2n}}{(2n+1)(2n+3)} \left(1 - n + 5n \frac{J_2}{e^2} \right), \quad (65)$$

and where

$$J_2 = \frac{1}{Ma^2} (I_{zz} - I_{xx}) = -\frac{\sqrt{5}R^3}{GMa^2} v_{2,0} = -\sqrt{5}C_{2,0}^{(a)}, \quad (66)$$

making use of Eqs. (58) and (47). From Eq. (65), it is clear that only the first few coefficients (say, up to $n = 5$) are significant for all applications, since $e^2 \approx 0.0066$ (Table 3). Also, the normal potential, comprising only even zonal harmonics, is independent of longitude and symmetric with respect to the equator.

Normal gravity (including the centrifugal acceleration) on the ellipsoid as function of *geodetic* latitude, ϕ (angle of the perpendicular to the ellipsoid with respect to the equator), is given by the Somigliana formula (Moritz 1980):

$$\gamma(\phi) = \frac{a\gamma_a \cos^2 \phi + b\gamma_b \sin^2 \phi}{\sqrt{a^2 \cos^2 \phi + b^2 \sin^2 \phi}}, \quad (67)$$

where normal gravity on the equator and at the poles is:

$$\gamma_a = \frac{GM}{ab} \left(1 - m - \frac{m}{6} \frac{e'q'_0}{q_0} \right), \quad (68)$$

n	J_{2n}
1	1.08263E-03
2	-2.37091222E-06
3	6.08347E-09
4	-1.427E-11
5	1.2E-14

$$\gamma_b = \frac{GM}{a^2} \left(1 + \frac{m}{3} \frac{e' q'_0}{q_0} \right), \quad (69)$$

with $m = \omega_e^2 a^2 b / GM$, $e' = E/b$ (the second eccentricity) and

$$\begin{aligned} q_0 &= \frac{1}{2} \left(1 + \frac{3}{e'^2} \right) \tan^{-1} e' - \frac{3}{2e'}, \\ q'_0 &= 3 \left(1 + \frac{1}{e'^2} \right) \left(1 - \frac{1}{e'} \tan^{-1} e' \right) - 1. \end{aligned} \quad (70)$$

At points along the perpendicular to the ellipsoid, the following approximate formula for normal gravity as a function also of ellipsoidal height, h , is often used:

$$\begin{aligned} \gamma(\phi, h) &= \gamma(\phi) \\ &\times \left(1 - \frac{2}{a} (1 + f + m - 2f \sin^2 \phi) h + \frac{3}{a^2} h^2 \right). \end{aligned} \quad (71)$$

which is accurate to $1.4 \times 10^{-6} \text{ m/s}^2$, or better, up to altitude, $h = 20,000 \text{ m}$, above the ellipsoid.

Earth's Internal Gravitational Field

While Earth's external gravitational field may be determined entirely from measurements and potential theory, the internal field is much less accessible to measurements and depends on models of the subsurface structure that can only be inferred from surface measurements and constraints provided by various other geophysical observations. Some have likened the study of the Earth's interior to the study of the cosmos – the investigator is incapable of performing in situ measurements and is left to use diverse (and sometimes ingenious) proxies to infer the Earth's interior makeup. Of course, there are borehole measurements and these are probing ever deeper into the Earth's crust, but they are isolated and expensive. A complete reconstruction of the Earth's (deeper) interior comes at present primarily from seismological data by analyzing the travel times of hundreds of thousands to millions of compressional (P) and shear (S) waves as they pass through Earth's body. Near-surface reconstruction also relies on seismic sounding (seismograms from intentional explosions) as well

gravimetry, magnetometry, and other geophysical sensors, including ground-penetrating radar, electromagnetic induction, and electric resistivity methods.

We may argue that knowledge of the interior gravity field is of secondary importance to an understanding of Earth's internal structure inasmuch this knowledge is derived from an Earth model that is already determined from other data. Only when gravity can be measured within the Earth (e.g., in boreholes) does the interior gravitational field offer a contributory importance to our modeling of the Earth's interior. At present, the deepest borehole in the world, at just over 12,260 m, is located in Russia on the Kola Peninsula on the Barents Sea north-east of Finland. Most holes are drilled for geological exploration and reach depths of several hundred meters.

Nevertheless, it is of interest to compute the gravitational attraction along a radius of the Earth, as modeled by a radially layered composite of mass density. From Eq. (8), it is easily shown that the gravitational potential inside a radially symmetric body (having radius, R) has the form:

$$\begin{aligned} V(r) &= \frac{4\pi G}{r} \int_0^r \rho(r') r'^2 dr' + 4\pi G \int_r^R \rho(r') r' dr', \\ 0 &\leq r \leq R. \end{aligned} \quad (72)$$

Thus, the gravitational acceleration is given by:

$$g(r) = -\frac{d}{dr} V(r) = \frac{4\pi G}{r^2} \int_0^r \rho(r') r'^2 dr'. \quad (73)$$

For the Preliminary Reference Earth Model (PREM) of 1981 (Dziewonski and Anderson 1981; Dziewonski 1989), which consists of approximately 80 layers, the radial variation of gravitation is shown in Fig. 3 together with the change in density.

On a more local scale, we may use the attraction of an infinite horizontal plate of constant density, ρ_0 , as a model to approximate the value of gravity in the crust (or ocean) near the Earth's surface. The attraction of such a plate of thickness, d , anywhere above or below the plate is:

$$B = 2\pi G \rho_0 d, \quad (74)$$

which is also known as the Bouguer plate effect. Suppose that g_P is the value of gravity at a surface point, P , on the Earth. Assuming that the topography is relatively flat in its vicinity, removal of a plate of material with density, ρ_0 , and thickness, d , diminishes the gravity value at P by B . Now bring the gravity value to the level d through free space using a normal gradient approximation, which changes its value by $F \approx -(\partial\gamma/\partial h)d$ (also known as the free-air reduction). Finally,

Gravity Field of the Earth,

Fig. 3 Gravitation and mass density inside the Earth according to the radially symmetric PREM

restore the material plate, which again decreases the value of gravity, now at depth, d , by B .

The resulting gravity as a function of depth thus becomes:

$$g(d) \approx g_p - \left(\frac{\partial \gamma}{\partial h} + 4\pi G \rho_0 \right) d. \quad (75)$$

Using nominal values for the normal gradient, $\partial \gamma / \partial h \approx -0.3086$ mGal/m (where $1 \text{ mGal} = 10^{-5} \text{ m/s}^2$), and the ocean water or crust density, $\rho_w = 1027 \text{ kg/m}^3$ or $\rho_0 = 2670 \text{ kg/m}^3$, respectively, this becomes:

$$g(d) \approx g_p + 0.2225d \text{ [mGal]}, \quad (76)$$

d in units of meter below sea surface;

$$g(d) \approx g_p + 0.0848d \text{ [mGal]}, \quad (77)$$

d in units of meter below land surface.

This is also known as the Poincaré-Prey reduction and may be used to model gravity in boreholes and in the oceans, given gravity at the surface. The model of gravity within the Earth's upper crust (or ocean) can be improved with more careful modeling of the effects of variable topography and variable density (especially in the oceans).

Summary

The Earth's gravitational field, defined as the field generated by the subsurface mass density, embodies a wealth of geophysical information at global and local scales. The external global field is often described in terms of a spherical harmonic expansion, where the low-degree harmonics have a definite (though incomplete) interpretation with respect to the moments of the density distribution. The attenuation of the potential in its spherical harmonic (spatial frequency) domain

is sufficiently gradual that first- and second-order radial derivatives readily characterize the local, near-surface structure of the Earth. Whereas the external gravitational field of the Earth can be modeled in detail on the basis of surface measurements and potential theory, the deeper internal gravitational field model is derived secondarily from density distribution models obtained from other sources, such as seismological data.

Definition

Observing the Earth from space over the past 50 years has resulted in spectacular advances in various areas of the

geosciences. This is the case, in particular, for measuring the precise shape of the Earth and its broad-scale internal structure from detailed measurements of the planet's gravity field. Since the early 1970s, tracking the orbits of tens of satellites at different altitudes and orbit inclinations has gradually improved our knowledge of Earth's average (static) gravity field (see section on "Gravity and Satellites"). Besides the precise description of the static component, attempts have been made to detect temporal variations of the gravity field. For example, a secular decrease of Earth's flattening (the degree 2, order 0 term) was discovered by precise analysis of the Lageos satellite laser ranging observations (Yoder et al. 1983) and attributed to the Global Isostatic Adjustment (GIA), the viscoelastic response of the crust and mantle after melting of ice at end of the Last Glacial Maximum (LGM) (Peltier 2009). Seasonal variations of the low-degree terms of the Earth's gravity field expansion (up to ~degree 6) have been detected from analysis of satellite orbital perturbations (Cheng and Tapley 2004). These variations were attributed to seasonal transfer of air mass inside the atmosphere as well as annual fluctuations of snow and land water storage (e.g., Cazenave et al. 1999). However, temporal changes of only the longest-wavelength (lowest degree) spherical harmonic (also called Stokes) coefficients could be monitored from orbital perturbations. This limited effective spatial resolution of observed mass change to several thousand kilometer, because large uncertainty in higher degree coefficients prevented detection of any time-varying signal.

Since 2002, the US–German jointly sponsored Gravity Recovery and Climate Experiment (GRACE) mission has been providing a precise survey of Earth's time-variable gravity field, with unprecedented temporal and spatial sampling (Tapley et al. 2004). GRACE time-variable gravity fields provide a means of measuring temporal and spatial variations of mass redistribution within the Earth system. The GRACE mission has launched a new era in studying a series of geophysical problems ranging from deep Earth structure to tracking mass redistribution on and near the surface of the Earth. GRACE has greatly improved our understanding of mass redistribution in various compartments of the climate system (atmosphere, oceans, terrestrial water, and cryosphere) and fundamentally enriched a number of fields, including (but not limited to) the global water cycle and land hydrology, mass balance of polar ice sheets and mountain glaciers, ocean mass and global sea level change, and solid Earth geophysics.

The GRACE Mission (2002–2017)

Launched in March 2002, GRACE utilized a state-of-the-art technique to observe variation of Earth's gravity by tracking the inter-satellite range and range rate between two coplanar, low-altitude satellites via a K-band ranging system (Tapley

et al. 2004). In addition, each satellite was equipped with a SuperSTAR accelerometer, GPS receiver/antenna, star cameras, and laser retro-reflector to complete the complement of science instruments. The GRACE Science Data System used the range and range rate data, along with ancillary data, to estimate a new gravity field every month, in the form of corrections to a well-defined background gravity model used in the data processing procedure. The monthly sampling rate has been selected in order to accumulate sufficient observations to ensure spatial resolution of about 400 km. Generally, there is a trade-off in selecting the temporal sampling interval. Accumulating data over longer time intervals increases spatial resolution but decreases temporal resolution and vice versa.

Modeling Temporal Geoid Variations

The static component of the gravity field G_0 corresponds to nearly 99% of the total field, mainly due to solid Earth contributions. This term can be easily evaluated and removed by computing the temporal mean of a long enough series of GRACE monthly geoids or alternatively considering a single geoid computed with a long period of time of satellite observations. The monthly time-variable geoid $\delta G(t)$ can merely be computed as the difference between the monthly geoid $G(t)$ measured by GRACE at time t and the static mean field component:

$$\delta G(t) = G(t) - G_0 \quad (1)$$

Thus, the corresponding geoid differences (also called monthly GRACE geoids in the following) only reflect short-term geoid change associated with mass redistributions inside the Earth system.

Let $\delta C_{nm}(t)$ and $\delta S_{nm}(t)$ be the time-variable “normalized” Stokes coefficients of the spherical harmonic expansion of geoid height, where n and m are the degree and order, respectively. Thus, the time-variable geoid is classically expressed as (Heiskanen and Moritz 1967):

$$\delta G(t) = \sum_{n=1}^N \sum_{m=0}^n (\delta C_{nm}(t) \cos(m\lambda) + \delta S_{nm}(t) \sin(m\lambda)) P_{nm}(\cos\theta) \quad (2)$$

where N is the maximum degree of the harmonic decomposition, θ is the colatitude, λ is the longitude, and P_{nm} is the associated Legendre polynomial which is dimensionless.

GRACE geoids are further expressed in surface mass change (usually in equivalent water height) assuming that mass redistribution occurs in thin surface layers compared

to the Earth’s dimension (Swenson and Wahr 2002), so that:

$$\begin{pmatrix} \delta C_{nm}(t) \\ \delta S_{nm}(t) \end{pmatrix} = \frac{(1+z_n) \text{Re}^2}{(2n+1)M} \iint_S \delta q(\theta, \lambda, t) \begin{pmatrix} \cos \\ \sin \end{pmatrix} (m\lambda) P_{nm}(\cos\theta) \delta S \quad (3)$$

where $\delta q(\theta, \lambda, t)$ is a surface density of surface water/ice/air mass, expressed in terms of equivalent water thickness at time t , whose harmonic coefficients, $\delta A_{nm}(t)$ and $\delta B_{nm}(t)$, can be evaluated from the corresponding geoid anomaly coefficients through the linear filtering:

$$\begin{pmatrix} \delta C_{nm}(t) \\ \delta S_{nm}(t) \end{pmatrix} = W_n \begin{pmatrix} \delta A_{nm}(t) \\ \delta B_{nm}(t) \end{pmatrix} \quad (4)$$

W_n is an isotropic spatial filter that weights the surface density coefficients, and its analytical expression is (Swenson and Wahr 2002):

$$W_n = \frac{2\pi G \text{Re} \rho_w}{(2n+1)\gamma(\theta)} (1+z_n) \quad (5)$$

In Eqs. (3) and (5) above, z_n represents the Love numbers that enables to take into account instantaneous elastic compensation of the Earth’s surface to the load; $\gamma(\theta)$ is the normal gravity on the reference ellipsoid at colatitude of θ . G ($\sim 6.67 \cdot 10^{-11} \text{ m}^3 \text{kg}^{-1} \text{s}^{-2}$) is the gravitational constant, M is the total mass of the Earth ($\sim 597602 \cdot 10^{24} \text{ kg}$), and Re ($\sim 6378 \text{ km}$) is Earth’s mean radius. ρ_w ($\sim 1000 \text{ kgm}^{-3}$) is the water density. Equations (4) and (5) are used to compute surface density variations $\delta q(\theta, \lambda, t)$ (or mass redistribution due to air, water, and ice mass change in surface fluid envelopes) from the monthly geoid harmonic coefficients.

GRACE Data Errors

Assessing the errors of GRACE monthly solutions was a major challenge. Two categories of errors were recognized: (1) errors introduced by data processing (errors of GRACE measurements and models used to remove other geophysical signals) and (2) post-processing errors (e.g., spatial smoothing of the GRACE solutions to remove high-frequency noise and leakage errors due to signal contamination from regions outside the studied area). Among errors in category (1), correlated errors due to un-modeled effects and contamination of other geophysical signals during data processing are highly problematic. Because of the limited spatiotemporal sampling provided by the GRACE satellites, these errors are aliased into the estimated spherical harmonic coefficients, giving rise to north–south stripes evident in the raw GRACE geoid and

mass maps. To reduce this organized spatial noise (category 1 error), a decorrelation filter has been proposed (Swenson and Wahr 2006), which can help suppress GRACE striping noise. Post-processing error arises mainly from two sources. One is from the limited degree and order of Stokes coefficients GRACE can provide, i.e., the truncation of GRACE gravity Stokes coefficients, typically at degree 60 or 96. The other is from the needed Gaussian smoothing to further remove the residual noise (after the decorrelation filtering). These post-processing errors significantly affect GRACE estimates of surface mass change by reducing signal amplitude at the higher degrees and orders and result in signal contamination into surrounding regions (called “leakage”). The GRACE orbital configuration (altitude and inter-satellite distance) and the need for spatial filtering and smoothing are the main factors that limit GRACE spatial resolution, estimated to be on the order of 300–400 km.

Another problem in the data processing arises from geocenter motion, i.e., the motion of the mass center of the Earth system with respect to origin of the terrestrial reference frame. GRACE gravity solutions are defined in a center of mass reference frame. Thus the degree 1 coefficients of the spherical harmonic expansion (representing geocenter motion) are missing in GRACE solutions. Independent estimates of geocenter motion from other geodetic techniques are needed (to be added to GRACE solutions), in order to accurately quantify longest-scale mass changes in the Earth system. In addition, the degree 2, order zero term is not well resolved by GRACE and traditionally is replaced by estimates based on satellite laser ranging. The accuracy of monthly GRACE solutions is estimated to be ~2 cm of equivalent water height change over areas exceeding one million square kilometer (e.g., Wahr et al. 2006).

Figure 1 shows a map of mass trends over global continental areas from GRACE over the period April 2002 to June 2017, computed from least-squares fit to time series at every grid point. Units are in cm of equivalent water height change per year. This map shows predominantly water mass gain or loss in major river basins and ice mass loss in ice-covered regions including ice sheets, and glaciers, and mass trends due to solid Earth geophysical effects, e.g., the strong GIA signals in the Hudson Bay in Canada and Scandinavia in Northern Europe, and seismic deformations due to major earthquakes (e.g., the 2004 Sumatra–Andaman and 2011 Tohoku–Oki earthquakes).

Applications of GRACE

In this section, we present a few examples of present-day mass variations detected by GRACE over continental river basins, Greenland and Antarctic ice sheets, and over the

oceans. The capability of GRACE in measuring solid Earth mass changes (e.g., GIA and co-/post-seismic deformations due to large earthquakes) is also briefly discussed.

Hydrology

The global water cycle that exchanges water among oceans, atmosphere, and land plays a key role in the physical and chemical processes that influence Earth’s climate and its change over time. On land, terrestrial water storage (TWS) change, as a major component of the global water cycle, reflects changes in water stored in rivers and lakes, soil, snow, and groundwater reservoirs and is closely connected to accumulated precipitation (P), evapotranspiration (ET), and surface and subsurface runoff (R) within a given area or basin, through the water balance equation relating a change in TWS in unit time Δt .

$$\frac{\Delta TWS}{\Delta t} = P - ET - R \quad (6)$$

For most land areas (not covered by snow), TWS is virtually a measure of total water content in surface reservoirs (rivers and lakes), soil layers, and groundwater reservoirs and is also a good indicator of abnormal climate conditions, such as droughts and floods. Accurately quantified TWS change provides a key measure of the continental water cycle and available water resources in a given region or river basin. However, estimating TWS change from in situ networks is difficult due to the lack of groundwater and soil moisture observations, which often are simply nonexistent at basin or smaller scales.

GRACE data have been successfully applied to the study of global and basin scale TWS changes (e.g., Wahr et al. 2004). Early studies mostly focused on the seasonal cycle and showed good agreement with estimates from global hydrological models. The extended GRACE time series also provide estimates of interannual and long-term variability in TWS. For example, several studies have detected severe drought events in different regions of the world, e.g., the Amazonia drought in 2005 (Chen et al. 2009) and Australia millennium drought (Leblanc et al. 2009). Anthropogenic effects on the terrestrial water cycle, such as groundwater pumping, are also detectable by GRACE (e.g., Rodell et al. 2009). Other studies have used GRACE TWS in combination with additional information to estimate changes in vertical or horizontal fluxes, e.g., $P - ET$, ET , or R , of the right-hand side of the water balance equation (Eq. 6) (e.g., Ramillien et al. 2006).

Land Ice Loss from GRACE

GRACE satellite gravity measurements offer a unique opportunity to directly estimate land ice loss and its contribution to

the global mean sea level rise. Land ice loss includes glacier melting and mass decrease of Greenland and Antarctic ice sheets. Numerous studies have been published during the last decade to provide estimates of the mass balance of Greenland and Antarctica and indicate a clear acceleration of ice mass loss from both ice sheets (e.g., Velicogna and Wahr 2006; Chen et al. 2006). Ice sheet mass loss explains about 30% of the global mean sea level rise of the last 15 years (WCRP Global Mean Sea Level Budget Group 2018). GRACE satellite gravity measurements have also been widely used to study ice mass change of mountain glaciers (e.g., Tamisiea et al. 2005). However, the quantification of mountain glaciers ice mass change is more challenging, limited by GRACE resolution. Optimal data processing methods, such as regional mascons or forward modeling, are needed to appropriately address GRACE leakage issue.

Ocean Mass Change

Net water flux into and out of the ocean causes its mass to change. Such changes cause gravitational variations detectable by GRACE (e.g., Chambers et al. 2004). This has allowed, for the first time, direct estimates of the global ocean mass contribution to sea level change. However, GRACE is also sensing GIA effect. On average over the oceanic domain, this effect is large and of the same order of magnitude as the ocean mass change due to present-day land ice melt itself. As GIA models vary significantly from each other with respect to this effect (e.g., Peltier 2009), GRACE ocean mass rates combined with land ice melt rates can place an independent constraint on the GIA correction.

Satellite altimetry allows precise measurement of present-day global mean sea level changes (e.g., Stammer and Cazenave 2018). The two main causes of the global mean sea level rise are ocean thermal expansion and ocean mass increase. GRACE is now routinely used to estimate the latter component, allowing assessment of closure/non-closure of the global mean sea level budget, when combined with satellite altimeter sea level measurements and Argo floats ocean temperature and salinity observations (e.g., WCRP Global Sea Level Budget Group 2018).

GIA Effect

GIA (also called postglacial rebound) represents large-scale viscoelastic readjustment (mostly rebounding) of Earth's crust and mantle following the removal of ice loads at the end of the LGM (Peltier 2009). GIA induces secular changes in the gravity field observable by GRACE. The large positive mass trend centered over the Hudson Bay (Canada) shown in Fig. 1 is one of the most prominent signatures of this process. Comparison between GRACE and other measures of GIA (e.g., surface gravity change, vertical crustal motions, model

estimates of ice load extent and melting history) has confirmed that GRACE is detecting Earth's recovery following melting of the Laurentide Ice Sheet at the end of the LGM (e.g., Tamisiea et al. 2007).

Coseismic and Post-seismic Deformations Due to Large Earthquakes

Besides GIA and the refinement of Earth's static gravity field, GRACE has contributed to the understanding of other solid Earth processes. In particular, GRACE appears able to detect the seafloor deformation, afterslip, and viscoelastic relaxation associated with large earthquakes. This is the case with the Sumatra–Andaman earthquake (magnitude of 9.3) of December 26, 2004, the largest recorded seismic event in about 40 years. GRACE successfully detected the gravity change associated with the corresponding coseismic subduction and uplift, in agreement with model predictions (e.g., Han et al. 2006). Co- and post-seismic deformations of another major earthquake, the 2011 Tohoku–Oki earthquake (magnitude of 9.0), have also been captured by GRACE (Li and Shen 2015). The seismic (mainly post-seismic) deformations of these two gigantic earthquakes have been illustrated in Fig. 1.

Summary

Since 2002, the US–German GRACE (Gravity Recovery and Climate Experiment) mission has been providing a precise survey of Earth's time-variable gravity field, with unprecedented temporal and spatial sampling. The first GRACE mission ended in 2017, but a new GRACE mission (GRACE Follow-On) was launched in May 2018, providing continuity in measuring the time-variable gravity fields, hence the spatiotemporal variations of mass redistributions within the Earth system. The GRACE missions have launched a new era in studying a series of geophysical problems ranging from deep Earth structure to tracking mass redistribution on and near the surface of the Earth. GRACE has greatly improved our understanding of mass redistribution in various compartments of the climate system (atmosphere, oceans, terrestrial water, and cryosphere) (Cazenave and Chen 2010; Rodell et al. 2018; Tapley et al. 2019). GRACE has fundamentally enriched a number of Earth science fields, including (but not limited to) the global water cycle and land hydrology, mass balance of polar ice sheets and mountain glaciers, ocean mass and global sea level change, and solid Earth geophysics.

Synonyms

Earth's dynamic gravity field; Temporal variations of the Earth's gravity

Definition

Temporal gravity changes Variation of Earth's gravity field with time due to various tidal, oceanic, atmospheric, hydrological, glaciological, volcanic, seismic, and tectonic processes.

Tidal gravity changes The periodic variation of gravity field due to the attraction of Sun and Moon.

Non-tidal gravity changes Gravity changes unrelated to the attraction of Sun and Moon.

Introduction

The gravity field of the Earth is an attraction force exerted by the Earth on any unit mass normal to the equipotential surface. It is a function of mass distribution and its spatial location, inside, on, and above the Earth's surface, following the Newton's law of gravitation. Continuous changes in the Earth system and its fluid envelopes related to the solid and ocean tides, oceanic circulation, atmospheric changes, hydrological changes, volcanic, seismic and tectonic activity, Earth's polar motion, Earth's inner and fluid core motions redistribute the mass and produce variations in the Earth's gravitational field on a large range of spatial and temporal scales (Fig. 1). The variation in the gravity field on timescales of thousands to millions of years caused by redistribution of mass due to the processes that shape the Earth's surface is termed “static gravity field” as this change does not occur over human timescale.

Temporal variations of Earth's gravity field are determined by measurements of the gravitational field at the same location with time. Surface measurements of time-varying gravity field started in the twentieth century using spring type relative gravity meters that were mainly employed to study tidal related gravity changes. Gravity changes can now be precisely recorded by terrestrial measurements using absolute gravity meters (AG), superconducting gravity meter (SG), relative gravity meter, or a combination of them (AG is the most precise instrument available that can measure the absolute gravity field with an accuracy of 1–3 μGal ($1 \mu\text{Gal} = 10^{-8} \text{ m s}^{-2} = 10 \text{ nm s}^{-2}$)) (Niebauer et al. 1995). SG can measure changes in the Earth's gravity field with 0.1 μGal accuracy (Hinderer et al. 2015a). A strong effort to monitor the time-varying gravity field globally has been made with the launch of the GRACE satellites in 2002 (Wahr 2007) and more recently by GRACE-Follow On mission in 2018 after the end of the GRACE mission (2002–2017). Precise measurements of the changes in the Earth's gravity field either by satellite (NRC 1997; Wahr 2007) or from surface measurements (Hinderer and Crossley 2000; Crossley et al. 2013) thus offer the possibilities to constrain the underlying causes of dynamic changes of mass distribution in the Earth system processes. Both measuring methods have some advantages and drawbacks. For example, localized gravity changes (i.e., effect due to injection of water in oil field) cannot be detected in satellite measurements, and similarly gravity changes occurring over a large region, particularly over remote areas, cannot be mapped using surface measurements. An attempt is

Gravity Field, Time Variations from Surface Measurements, Fig. 1 Schematic diagram showing temporal gravity changes that can be studied from surface gravity measurements ($1 \mu\text{Gal} = 10^{-8} \text{ m s}^{-2} = 10 \text{ nm s}^{-2}$)

made to intercompare the satellite-derived gravity fields with surface gravity measurements observed with SG despite the fact that the ground and space gravity measurements are not sensitive to the same effects. Radial displacement is important for ground observations but has no effect on satellites, and ground gravity measurement is a point measurement while satellite measurements are integrated response over a large region (typically a few hundreds of kilometers; Wahr 2007). Nevertheless, first results of intercomparison of gravity changes observed by the European SG network and GRACE satellite data reported a fair agreement in the time-varying gravity field originated due to hydrological changes (Crossley et al. 2012; Hinderer et al. 2006).

Concepts and Applications

Primarily there are two categories of time-varying gravity signals: one that varies periodically and another one that is nonperiodic. Periodic gravity changes such as tides can be separated from the observations based on their periodicity but nonperiodic changes that arise from combinations of different contributing sources are difficult to recognize. However, they are identified using other complementary information. There are about 30 SGs in the world, which are continuously measuring gravity changes and form the international network

IGETS (International Geodynamics and Earth Tide Service) (Voigt et al. 2016) formerly called GGP (Crossley et al. 1999). IGETS stations are sparsely distributed worldwide with a very few stations in the southern hemisphere and in the equatorial band. These data are shared within the network for various applications and are also used for comparison with satellite-derived gravity changes that allows upscaling of terrestrial data and downscaling of satellite data (Hinderer et al. 2015a) for broader understanding of causes of gravity changes. AG measurements are also made at these locations for calibrations of SGs and for cross validation of secular changes. Both instruments (AG and SG) are essentially laboratory instruments; however, AG can be transported but SGs are mostly observatory instruments dedicated to continuous measurements over long durations. In the hybrid gravity approach (Hinderer et al. 2016), a combination of different surface gravity measurements is used to estimate spatiotemporal changes in Earth's gravity field. Details of surface gravity measurements, their accuracy, and potential application, as suggested by Crossley and Hinderer (2005) with minor modifications, is summarized and presented in Table 1.

The following sections present a brief description of the main sources of gravity changes that are recorded by surface gravity measurements and used to study the sources responsible for these changes. An example of different contributions (solid tides, polar motion and length of the day, atmospheric

Gravity Field, Time Variations from Surface Measurements, Table 1 Types of surface gravity measurements and their potential applications in studying time variable gravity field

	Absolute gravity meter (AG: Micro-g Solutions, FG 5)	Superconducting gravity meter (SG: GWR type)	Relative gravity meters (RG: Scintrex, CG3M, CG5M)
Precision	$\leq 1 \mu\text{Gal}$	$0.001 \mu\text{Gal}$	$1 \mu\text{Gal}$
Accuracy	$1\text{--}3 \mu\text{Gal}$	$0.1 \mu\text{Gal}$	$10 \mu\text{Gal}$
Drift	0	$0.01\text{--}0.05 \mu\text{Gal/day}$ (variable)	$3\text{--}10 \mu\text{Gal/day}$ (variable)
Setup time and operation	AG is a transportable instrument that operates in a controlled temperature environment. It can be set up in 1–3 h. One to three days measurements are desirable to get best results	Setup of SG requires a few days and some weeks to stabilize. It is housed at one place and needs calibration and drift monitoring by AG for better accuracy	RG is a field instrument that can be set up in a few minutes. A network of stations is used for measurement loops. Requires repeated measurements at a reference station every few hours
Dominant noise	Microseismic and man-made noise	Environmental effects	Environmental effects, microseismic noise, vehicle shaking, drift
Possible applications	Tidal, hydrological changes, pre-co-post seismic changes, glacial isostatic adjustment, tectonics, oil, gas, and geothermal reservoir monitoring, volcanic mass changes	Tidal, polar motion, hydrological changes, atmospheric and ocean loading's core processes, pre-co-post seismic changes, free oscillation of the glacial isostatic adjustments, volcanic mass changes	Tidal, hydrological changes, co-seismic changes for large quakes, volcanic mass changes

loading, tidal and nontidal ocean loading, soil moisture, and snow loading) to the time-varying gravity in Strasbourg is presented in Fig. 2. The amplitude of the solid tides and the ocean tidal loading would be ten times larger compared to plotted amplitudes in the Fig. 2, where only long-period tides are considered.

Tides

Tidal gravity changes are caused by the attraction of other planetary bodies like the Sun and Moon. The attraction of these planetary bodies deforms the Earth's solid and fluid surface and produces changes in the gravity field. These changes are periodic, mainly semi-diurnal and diurnal, but also with long-period components (fortnightly, monthly, half-yearly, and yearly as shown in Fig. 2). The semi-diurnal and diurnal tides can be very large (with peak to peak value of $\sim \pm 150 \mu\text{Gal}$) according to the station location and usually are the largest contribution in any surface gravity measurements. They can be computed accurately and therefore can be removed from observed gravity changes to study nontidal gravity changes (Wenzel 1996). The precise tidal gravity changes are measured with SGs, AGs, and other surface gravimeters (Hinderer et al. 2015a) on land and are recorded in satellite altimetry data over the oceanic region (Wahr 2007). Tidal gravity changes are the elastic response of the Earth to the tidal forces and hence, modeling of tidal gravity changes provide information on the internal structure and properties of the Earth as its elastic transfer function varies according to the internal distribution of density, compressibility, and rigidity parameters. The very long observational duration of some SGs of the IGETS international network exceeding for instance 25 years for the Strasbourg station

leads to the detection of tidal waves of very small amplitude that were previously hidden in noise for shorter records (Ducarme 2011; Calvo et al. 2016). Tidal observations also provide independent evidence of general relativity theory of planetary movements (Warburton and Goodkind 1976).

Sea Level Variation

Non-steric redistribution of ocean mass causes non-negligible changes in the Earth's gravity field. These are commonly recorded in satellite altimetry data. Movement of ocean waters also affects gravity changes inland; this may be quantified using results from satellite altimetry data (Fukuda and Sato 1997). It is reported that gravity changes caused by sea level change deducted from satellite altimetry data are of the order of few μGal near coastal regions that can be observed in SG data (Virtanen and Mäkinen 2003; Kroner et al. 2009).

Atmospheric Pressure

Atmospheric pressure changes alter surface gravity values because of the redistribution of mass in the atmosphere (attraction force) and the surface loading (elastic deformation) due to the change in the surface mass (Kroner and Jentzsch 1999; Boy et al. 2002; Hinderer et al. 2014). The induced gravity changes are in the order of $\pm 5 \mu\text{Gal}$ (Fig. 2) and can reach up to $10\text{--}15 \mu\text{Gal}$ for large pressure fronts ($30\text{--}50 \text{ hPa}$). They are often estimated using a simple atmospheric admittance function between gravity and atmospheric pressure, that is, $0.3 \mu\text{Gal/hPa}$ (Crossley et al. 1995). These effects are generally considered as noise in gravity data and corrected using local barometric pressure data. More sophisticated

Gravity Field, Time Variations from Surface Measurements, Fig. 2 Various contributions to time-varying gravity in Strasbourg, France (Courtesy: J.-P. Boy; $1 \mu\text{Gal} = 10 \text{ nm s}^{-2}$). Note that the

amplitude of the diurnal and semi-diurnal solid tides and the ocean tidal loading would be ten times larger than plotted amplitudes, which are only long-period tides

models of surface gravity loading where the Newtonian attraction of atmospheric masses is computed based on the 3D spatial density distribution (as derived from three-dimensional weather models) are also available (Klügel and Wziontek 2009).

Polar Motion

The direction of the Earth's axis of rotation is not steady in space but rather varies with time with two dominant periods (1 year and 435 days); this motion is generally known as polar motion or oscillation of the rotation pole. The 435-day component is referred to as Chandler wobble by astronomers. This signal can be detected by various techniques (spectral analysis, least squares adjustment) in surface gravity using continuous and stable SG observations (Hinderer et al. 2006). The

related signals are of several μGal and change according to the station coordinates (Ziegler et al. 2016) (Fig. 2).

Free Oscillations of the Earth

Large quakes are known to excite the free oscillations of the Earth (Hinderer et al. 2015a; Arora et al. 2008), which lead to surface gravity changes in the seismic frequency band. These changes accompanying the eigenmodes occur at periods between a few hundreds of seconds and 54 min, which is the longest period of the free elastic oscillations of the Earth, and can be well investigated using SG records (Rosat et al. 2004; Rosat and Hinderer 2018). Besides, free oscillations unrelated to quakes but rather due to atmosphere–ocean–solid Earth interactions (termed “hum”) were first reported from the SG measurements at Syowa, Antarctica (Nawa et al. 1998).

More recently SG data have also been analyzed for the detection of gravitational waves (Coughlin and Harms 2014) or dark matter (Horowitz and Widmer-Schmidrig 2020).

Glacial Isostatic Adjustment

On long timescales the Earth behaves like a viscoelastic material and deforms when subjected to a load. Major changes in climatic conditions of the Earth, from its birth to the present, caused large-scale changes in strengthening and weakening of the ice sheets of the cold regions of the Earth's surface. The response of the Earth to the glaciations and deglaciations is known as Glacial Isostatic Adjustment (GIA). Land-based gravity measurements have provided useful constraints to GIA, for instance, in the North American region (Lambert et al. 2001), Greenland (van Dam et al. 2000), in Svalbard (Sato et al. 2006; Mémin et al. 2014), and in Alaska (Sato et al. 2012). One of the important properties of deep Earth that GIA can provide is information about the viscosity of the Earth materials.

Volcanic Mass Changes

The growth of the volcanic dome and fluxes of volcanic masses cause local gravity changes. Volcanic mass redistributions produce gravity change in the order of tens to hundreds of μGal and can be observed using any kind of surface measurements. Surface gravity measurements along with other geodetic measurements for surface deformation like GPS or InSAR (Interferometric Synthetic Aperture Radar) are prospective tools for the estimate of mass changes during the volcanic processes (Jousset et al. 2000; Carbone et al. 2017).

Crustal Deformation Associated with Earthquakes

Sudden displacements of faults during a quake cause redistribution of mass as well as change in the elevation, both leading to local gravity changes. An example of gravity changes before and after Haicheng quake, 1975, and the Tangshan quake, 1976, is reported by Chen et al. (1979). Later on there have been several studies that document co-seismic gravity changes in surface measurements with SGs (Imanishi et al. 2004) and also in GRACE satellite observations (Han et al. 2006; Tiwari et al. 2008; de Linage et al. 2009).

In the case of the large subduction Tohoku-Oki earthquake in 2011 of magnitude 9.0, GRACE data have allowed to reveal large-scale gravity changes due to aseismic mass fluxes of tectonic origin (Panet et al. 2018).

During the same earthquake there is also a transient gravity signal with a small amplitude (fraction of μGal) that has been

detected by an SG before the arrival of seismic waves (Montagner et al. 2016) opening new perspectives in earthquake seismology and early-warning systems.

Gravity records of silent and slow quakes, for example, from Cascadian subduction zone showing the concordance of gravity changes of about 10 μGal with episodic slip and seismic tremor activity (several times a year) is one of the interesting observations in temporal gravity changes (Lambert et al. 2006).

Hydrology

Variations in land water storage (surface water, ground water, soil moisture, and snow) induce variations in the gravity field recorded on the surface (Hinderer et al. 2015a). The contributions of soil moisture and snow at Strasbourg, France, are plotted in Fig. 2. The amplitude of gravity changes associated with seasonal hydrological changes are larger than secular changes (Tiwari et al. 2006; Hinderer et al. 2015) and sometimes spread over a large area that can be mapped only through satellite measurements (Tiwari et al. 2009) because large-scale variations are difficult to be evaluated using ground-based observations due to the lack of adequate sampling. Hydrological fluxes at different time and spatial scales can now be mapped by monitoring temporal gravity changes, which holds promise to provide closing water cycle on local and regional scale (Tapley et al. 2019). Studies using the European regional network of SGs demonstrated that surface measurements of the seasonal component of continental hydrology can help in validating the satellite missions like GRACE (Hinderer et al. 2006; Crossley et al. 2012; Weise et al. 2012) and also suggest the complementary nature of satellite and ground-based observations (Tiwari et al. 2014). In the recent years there have been many experiments using SG measurements in various catchments in order to monitor water storage changes at the local scale (from meters to hundreds of meters). Some of these catchments are at mid-latitudes like in Europe (Creutzfeldt et al. 2010; Fores et al. 2016; Naujoks et al. 2010) or close to the equator in West Africa (Hinderer et al. 2012; Hector et al. 2015). Recently differential gravity studies using two simultaneously measuring SGs help even further to investigate hydrological signals at the local scale (Kennedy et al. 2014).

Oil, Gas and Geothermal Reservoir Monitoring

Time lapse gravity measurements are regularly used for monitoring subsurface density changes due to the fluid motions of the injected water and gas in the reservoir for enhancing recovery as well as for sequestration of CO_2 gases (Hare et al. 1999; Alnes et al. 2008; Sugihara et al. 2013; Jacob et al. 2015). The amplitude of gravity changes is quite

appreciable in the region where injections are large and reservoir depth is small. Such changes in gravity field occur over injection time period and are generally in the order of few tens of μGal to hundreds of μGal depending on the volume of injection and depth of injection. An estimate of other sources of the gravity changes (e.g., water table, atmospheric changes) in the area of measurements is required to model injected mass precisely. Surface gravity is also used as a monitoring tool for geothermal reservoirs and helps in better understanding long-term sustainability of the resource (Sofyan et al. 2011; Oka et al. 2012; Hinderer et al. 2015b; Portier et al. 2018).

Summary

Measurements and modeling of time-varying gravity changes allow a better understanding of various phenomena, as discussed in the earlier sections. Isolating the individual contributions from the aggregate effect in the temporal series of gravity changes has been a major challenge over a long time. Nevertheless, as number of observations and complementary information of temporal gravity changes are increasing, different components of time series of gravity changes can be better separated. Above mentioned examples and discussion suggest that time-lapse or continuous surface gravity measurements can be utilized for a wide variety of geophysical processes that deform the Earth's surface and move mass inside, on, and above the Earth's surface causing the gravity field to vary with time. Surface measurements are also vital as they could provide a test, or validation, for satellite-derived temporal gravity changes.

Gravity Measurements, Absolute

Mark A. Zumberge

Institute of Geophysics and Planetary Physics, Scripps
Institution of Oceanography, University of California, San
Diego, La Jolla, CA, USA

Synonyms

Absolute acceleration due to gravity; Absolute *g*

Definition

Gravity	The mutually attractive force between any two masses.
Acceleration due to gravity, <i>g</i>	The value of the acceleration of a mass due to the force of gravity observed in a reference frame rotating with Earth.
Absolute	Measured with calibrated instruments traceable to metrologic standards. For the case of gravity, this requires length and time standards.
Absolute gravity meter or absolute gravimeter	An instrument used to measure gravity absolutely, traceable to time and length standards.

Introduction

The value of the acceleration due to gravity on Earth's surface, *g*, depends on position and time. A worldwide variability of roughly 0.5% from 9.8 m/s² is caused by Earth rotation, variations in density, and variations in geometry caused both by tidal fluctuations and tectonic deformation. Studying how *g* varies can reveal important facts about Earth as a whole and about a long list of local phenomena ranging from volcanic activity to evolution of oil and gas reservoirs.

Often scientists are interested only in changes in gravity with either position (gravity maps) or with time (time-lapse gravity). Many of these studies can be completed with simple, relative gravity meters which commonly consist of an electromechanical spring-mass sensor (Torge 1989). Relative gravity measurements (i.e., the difference in *g* between two sites) are more common because the interesting variations in *g* are small and its absolute value is not important for most geophysical applications. Almost all relative gravity meters undergo drift, however, making it difficult to separate real temporal gravity changes from drift in the sensor. Drift can be calculated and accounted for in cases where it is feasible to make redundant observations at multiple sites and assume gravity values at reference sites are constant. In a number of important cases, however, such drift compensating efforts are inadequate and absolute measurements are needed – they are inherently free from drift because of their reliance on length and time standards.

A note on units: practitioners in the field of gravity measurement use the unit *Gal* (after Galileo) which is defined as 1 cm/s². The nominal value of *g* is around 980 Gal. More common usage is the mGal (=10^{−3} Gal) and the μGal (=10^{−6} Gal or about 10^{−9} g). A precision of a few μGal is available from the best relative gravity meters (following a significant drift compensation effort within the measurement process) and 1 or 2 μGal with the best absolute gravity meters. Absolute determinations are characterized by both precision (the smallest observable signal or change) and accuracy (level of uncertainty or the discrepancy between the measured value and the unknown true value).

History

Late in the seventeenth century, it was discovered that a pendulum would swing with a slightly different period if it were moved to a different latitude. This effect, caused by gravity's dependence on latitude (primarily because of Earth rotation, causing both a centrifugal term and an elliptical shape to the planet as a whole), was used to make some of the earliest estimates of the deviation of Earth's figure from a sphere (Lenzen and Multhaus 1965). Two kinds of pendulum gravity meters, the reversible pendulum and the invariable

pendulum, provide a good example of the difference between absolute and relative sensors. A reversible pendulum, used extensively by Henry Kater in the nineteenth century, exploits the curious fact that two pivot points on an asymmetric pendulum which are found to yield equal oscillation periods are separated by the length of a simple pendulum (a point mass suspended from a massless rod) having that same period. This allows an absolute calculation of gravity based on the measurement of the pendulum period (referenced to a time standard) and the distance between the two oscillation points (referenced to a length standard) which have a common period, and is therefore an absolute measurement. Invariable pendulums, on the other hand, were simply swung around a single point and changes in gravity were observed as changes in the period. Pendulum measurements were made extensively by geodesists to refine the figure of the Earth and for mineral exploration up until the early twentieth century when electronic methods became adequately advanced to measure accurately the time needed for a mass in a vacuum chamber to fall a known distance. Cook (1965) and Faller (1963) pioneered some of the early free-fall measurement techniques. Towards the end of the twentieth century, the advent of the laser allowed for great improvements in absolute gravity measurement (Hammond and Faller 1967; Alasia et al. 1982; Zumbege et al. 1982; Niebauer et al. 1995).

Now, in the beginning of the twenty-first century, atomic methods are becoming viable. The most commonly used method today is to determine the acceleration of a mass freely falling in a vacuum by means of laser interferometry. Generally this has been done with macroscopic objects; however, this may be gradually replaced with a method using an ensemble of ultra-cold atoms, whose acceleration as they fall freely in a vacuum chamber is determined with matter-wave interferometry.

Principles of Modern Measurements

Macroscopic Falling Test Mass

Figure 1 is a schematic diagram of the mainstay of absolute gravity measurements since the mid-to-late twentieth century. A mechanical system inside a high vacuum chamber effects the release of a test mass. A retro-reflecting prism mounted to the test mass returns laser light entering and exiting the chamber through a window in the bottom. A beamsplitter (or half-silvered mirror) combines this reflected light with that similarly reflected from a fixed retro-reflector. The two reflected beams interfere with one another, evermore rapidly producing successive light and dark fringes as the falling mass accelerates. Two cycles of light-to-dark interference fringes are completed for each advance in the fall of a distance equaling the laser's wavelength. A photodetector senses the passage of interference fringes and generates an electrical

Gravity Measurements, Absolute, Fig. 1 A schematic diagram of a free-fall absolute gravity meter. A mechanical system (not shown) inside the vacuum chamber releases and catches the falling object. An interferometer determines the position of the test mass as it falls; the interference fringe signal is an increasing frequency sine wave

signal from which the local value of gravity (the rate at which the falling mass accelerates) can be calculated through appropriate timing analysis performed by a computer. Typically, the mass falls a distance of 10–20 cm and a thousand or more drops over a period of a day provide a statistical uncertainty of a few μGal . Because the measurement is based on calibrated length and time standards – the wavelength of the laser light and the frequency of the timing oscillator – the measurement is absolute.

Microscopic Falling Test Masses

A new and promising method for the absolute determination of gravity makes use of cold atom interferometry (Kasevich 2002). Toward the end of the twentieth century, physicists learned to use lasers to trap and manipulate clouds of atoms. Atoms can now be confined in an evacuated magneto-optical trap, cooled to very low temperatures with laser cooling, and then dropped or even launched vertically (again, with lasers) to create an “atomic fountain.” Exploiting the fact that all matter can be described as waves, atomic physicists have

learned to interfere atomic wave functions with one another and, in so doing, perform a number of highly precise measurements using them. In particular, because the phase of an atom's wave function depends on gravity, interfering atoms that have traversed separate paths through a gravitational field can yield an absolute measure of gravity. The first experiments performed by Kasevitch and Chu (1992) and followed by others (Peters et al. 2001; Lempore et al. 2008) required a laboratory full of complex optical, vacuum, and electronic equipment. Recently, however, the technology has advanced to a state where portability has been achieved (Merlet et al. 2010; Fang et al. 2016). A commercial version of a cold atom interferometric absolute gravity meter is currently available from Muquans (Talence, France).

Instrumentation

The mechanical details of conventional free-fall apparatuses vary. In some, the test mass's fall is initiated by a small elevator inside the vacuum chamber, which also surrounds the mass as it falls and acts as a shield against minute non-gravitational forces. In others, the mechanical system resides at the bottom of the vacuum chamber and launches the test mass upward, providing a mass in free flight, the acceleration of which can be measured during both its rise and fall. Another important variation is the use of a spring suspension system to isolate the reference reflector from vibrations.

Currently the most widely used absolute gravity meter is the model FG5, manufactured by Micro-g LaCoste (Lafayette, Colorado, USA) and shown in Fig. 2. With laser interferometry, it tracks the descent of a 300 g mass during a 15 cm drop. The portable system weighs 320 kg and can produce an absolute gravity value accurate to 2 μGal after an hour of data collection. Significant care has been taken by its developers to ensure that systematic errors – those whose signs do not vary and cannot be reduced by averaging – are less than the quoted accuracy. Such errors include forces on the falling mass other than gravity (e.g., residual air-drag and magnetic or electrostatic forces) and imperfections in the optical and timing systems. Periodically, many absolute gravity meters make measurements simultaneously in one of the world's standards lab for an intercomparison to test the assessments of the instruments' accuracies (Sasagawa et al. 1995).

The cold-atom interferometry method that is on the steep portion of the learning curve is schematically represented in Fig. 3. In this embodiment of the technology, developed by Muquans, a single laser cools and traps the atoms, then probes them with matter-wave interferometry during their free fall. A laser, tuned to a hyperfine transition in the falling atoms' electronic spectrum, is ramped in frequency to match the increasing Doppler shift experienced by the falling atoms as they accelerate under gravity. The rate that the probing laser's

Gravity Measurements, Absolute, Fig. 2 The micro-g LaCoste FG5 is a commonly used portable absolute gravity meter

frequency must be changed to exactly match the Doppler shift is controlled by the local value of gravity. Cold atom interferometry provides an extremely sensitive way to determine this rate of frequency shift. The system is smaller in size (100 kg) and similar in cost to a macroscopic free-fall apparatus, and it has no moving parts and can collect data at a rate of two samples per second. Figure 4 is a photograph of the Muquans device.

Applications to Geophysics

Near Earth's surface, the rate of change of gravity with altitude is about 3 μGal per cm. Therefore a detection of a gravity change of a few μGal yields information on cm-level height changes. Observing gravity changes together with height information obtained by other means can provide important information for modeling the causes of surface deformation. An increase in density of 0.1 g/cm^3 occurring throughout a 25 cm thick layer below the observer (such as might be caused by water saturation) increases gravity by 1 μGal . These changes can occur very slowly which makes it desirable to use absolute measurements to detect such changes. Examples of long time series of absolute gravity used to study geophysical phenomena include observations of postglacial rebound (Lambert et al. 2001), water flooding in a natural gas reservoir (Hare et al. 1999), vertical land movement near tide-gauges (Teferle et al. 2006), and observations of coseismic offsets from an earthquake (Tanaka et al. 2001).

Gravity Measurements, Absolute, Fig. 3 In a cold-atom interferometer gravity meter, a cloud of atoms falls freely while being probed with a tunable laser (after Muquans)

Gravity Measurements, Absolute, Fig. 4 A commercially available quantum gravity meter made by Muquans (Talence, France)

A very important geophysical application of absolute gravity measurement is the establishment of calibration lines for relative gravity meters (Sasagawa et al. 1989). Absolute g measurements are also necessary in certain metrology applications, including piston-cylinder pressure calibrations and in defining the standard kilogram (Robinson and Schlamminger 2016).

Summary

Absolute gravity measurements are much less common than those made with relative gravity meters. However, because of their freedom from drift, made possible through the use of modern atomic length and time standards, absolute g meters are extremely important for monitoring long term changes associated with crustal deformation and density change and for calibrating relative meters. New advances in atomic physics may result in an absolute gravity meter which is similar in size to typical relative gravity meters, advancing the use of absolute gravity measurements in geophysics.

Aerogravity; Airborne gravimetry

Definition

Airborne	Anything carried by a fixed wing aircraft, a helicopter, an airship, or an unmanned aircraft.
Aero	Anything related to the atmosphere above ground.
Gravity	In this context nonrelativistic mass attraction as defined by Newton.
Gravimetry	In this context the measurement of the gravity field variation by mass attraction.

Introduction

The law of gravity is one the most fundamental in natural sciences. Instruments for gravity measurements have been developed first for use on land surface, later for use on ships. The instruments used for maritime surveying needed a special platform to compensate the movements of the vessel that add additional components to the main value of the

measurement: the acceleration of a well-defined mass due the gravity field of the Earth. The same accounts for airborne applications of gravity meters: The aircraft's variations in roll, pitch, and yaw angles and height changes must be either compensated for or measured for later reductions and corrections. Therefore, most instruments used in the early stages of airborne gravity meter development were basically upgraded marine gravity meters (LaCoste 1967). Due to the problem of the fast aircraft movements and therefore the even larger accelerations implied, only after the practical implementation of a global satellite-based positioning system (as GPS) non-inertial navigation became precise enough to enable satisfactory corrections and reductions (Bruton et al. 1999). At present, three different categories of airborne gravity instruments evolved: scalar gravity meters, vector gravity meters, and gradient or full tensor meters. All instruments are used to measure the regional variation of the Earth's gravity field over often inaccessible areas in a quick fashion.

Principle Idea of Airborne Gravity

In the still most common airborne gravity applications, scalar gravity meters are used. Such meters usually measure only the relative vertical component of the Earth's gravity field using a mass coupled to a spring, a principle that was adopted from gravity land-based surveying (Fig. 1). In airborne gravity, much larger accelerations than the desired signal are introduced by attitude and height changes of the aircraft, carrying

the gravity meter. Beyond these inertial accelerations, vibrations occur that are usually damped by suitable mechanical or electromechanical means. The residual effect of the vibrations in the aircraft's cabin is usually dealt with as a noise signal. Therefore, we focus on the gravitational and inertial accelerations only. The instrument and the navigation equipment are placed in a rigid aircraft that defines the body frame. Within this body frame, we primarily measure the accelerations in the axes of the aircraft: forward, down, and sideward in a right-hand system. The gravity sensor is fixed on a platform that compensates some of the aircrafts forward and sideward accelerations that are coupled to attitude variations but not the vertical acceleration components. The main aim of the platform is to keep the gravity sensor in horizontal level in order to keep the measurement range and sensitivity of the gravity meter high. Additional navigation equipment as global positioning system antennas and inertial measurement units monitor the movements of the aircraft's body frame in the geodetic frame. Consequently, lever arms between the navigation measurement units and the gravity sensor must be corrected for in the body frame and the resulting accelerations and force must be transferred to the geodetic reference frame for later gravity mapping.

Attitude Compensation Platforms

Most platforms designed to carry a gravity sensor on a moving vehicle are two axes gimbal constructions to compensate

Gravity Method, Airborne, Fig. 1 Principle of airborne gravity

coupled roll, pitch, and yaw variations (LaCoste et al. 1967). The attitude information is commonly acquired by a gyro for short wavelengths and an accelerometer for wavelengths up to some minutes for each directional component. Some platforms compensate heading variations as well. Such platforms are Schuler-tuned. The platforms are designed to compensate attitude changes almost instantaneously in the dynamic range of the gravity sensor. Therefore, special filters are applied that define the platform period, which is usually in the order of some minutes.

Scalar Gravity Meters

Most meters in use for airborne gravity surveying are based on a test mass coupled to a spring or on torsion balance. Some new developments utilize superconductive gravity sensing systems. Such instruments measure the relative changes of the main vertical component of the Earth's gravity field. Beyond the residual platform errors, an independent non-inertial vertical acceleration determination is needed to reduce for the vertical accelerations of the body frame. This is possible only since global satellite-based positioning system navigation data is available. Scalar systems generally have a very low drift rate and therefore can be used for long wavelength gravity mapping as required for geodesy. The shortest detectable wavelengths are dependent on flight velocity, the dynamic range of the gravity sensor, and the platform period. Generally, some few mGal ($1 \text{ mGal} = 10^{-5} \text{ m/s}^2$) are achieved in accuracy related to some few kilometers wavelength resolution at an average speed of about 160 km/h above ground.

Vector Gravity Meters

Vector gravity meters are in most cases adapted inertial measurement units that measure the three vertical components of the Earth's gravity field in the body frame of the aircraft (Jekeli 2001). Analogue to most attitude-compensating platform designs, the signal is gathered from a combination of directional gyro and accelerometer measurements. In this configuration, global satellite-based positioning system navigation data must be applied for all directional acceleration reductions. The drift rates of such instruments are usually higher than those of scalar meters. At present, only very few systems are available, that are not only able to measure the significant vertical component but also the horizontal components in sufficient accuracy and resolution. Most vector gravity meters are not installed on an attitude-compensating platform but are placed on dampers only. The resolution and accuracy for the vertical component of available vector systems is better than those of scalar spring tension or torsion balance meters.

Gravity Gradient Meters

In order to enhance the short wavelengths resolution and the measurement accuracy significantly, gravity gradient meters were developed (Heiland 1940). The main idea is to eliminate the impact of the aircrafts attitudes and accelerations in the measurements by measuring the directional gradients directly. To achieve this, diagonally arranged pairs of highly accurate accelerometers are placed on a slowly rotating disk, one for each direction. Since the two accelerometers measure in opposite directions, the largest effects of the body frame accelerations are ruled out by the acceleration difference between the two accelerometers and mainly the directional gravity gradient remains. Such gradients are not stable enough for large-scale integration and therefore are only suitable for short wavelength detections in local to small-scale regional areas. This sensing system needs an exceptionally accurate attitude compensation platform. If all directional gradient components are measured, this system is called a full tensor gradient gravity meter. Available resolutions are in the order of 0.5–1 Eotvoes ($1 \text{ Eotvoes (E)} = 0.1 \text{ mGal/km} = 10^{-9} \text{ s}^{-2}$).

Processing, Reductions, and Corrections

The original data set is the sum of all measured accelerations in one or more components within the body frame of the aircraft. In order to get the gravity variation on flight level, the directional components of the body frame accelerations in a chosen geodetic frame have to be reduced for. As a next step, an Eotvoes correction has to be applied to compensate for the gravitational impact due to varying centrifugal forces (Harlan 1968). Next, a platform error correction has to be applied, usually a Harrison correction for scalar meters.

The gravity disturbance (gravity variation on ellipsoidal level) is determined by the normal gravity reduction and the free-air gravity reduction between observation level and ellipsoid.

In order to achieve the gravity anomaly, the same is done with reference to the geoid instead of the ellipsoid.

Applications and Aircraft

Airborne gravity can either be used to determine the regional geoid more precisely or for geophysical reconnaissance and prospection. For geodetic purposes rather high altitude straight and level fixed wing aircraft flights utilizing scalar gravity meters are most common (Forsberg et al. 1996). In geophysics, two aspects occur: large to mid-scale reconnaissance surveys to get an overview on tectonic or geological settings and small-scale prospection in search for mineral deposits or similar tasks (Veryaskin and McRae 2008). For reconnaissance, fixed wing aircraft with long-range capabilities are preferred. In prospection, high-resolution vector or gradient gravity meters are

used on small fixed wing aircraft, helicopters, or airships. First attempts to use unmanned airborne vehicles (UAV) are under way. New instrumental developments try to utilize modern superconductive meters, absolute gravity meters, or devices based on cold atom interferometry.

Summary

Airborne gravity has become a practical and accurate method to measure the variations of the Earth's gravitational field over regional areas. In geodesy, fixed wing aircraft equipped with scalar gravity meters are preferred. In geophysics, the same configuration is often used for reconnaissance surveys. For aerogeophysical prospection, low- and slow-flying aircraft are favored combined with vector or gradient gravity meters.

Gravimetry methods; Gravity and figure of the Earth

Definition

Gravity methods focus on the determination of the gravitational field of the Earth's body and its anomalies and shape (determination of the figure of the Earth). The figure of the planet is essentially characterized by two forces: attraction and centrifugal force. Gravitation is a general property of all matter and is independent of the chemical composition of mass particles. The mathematical description of the gravitational field goes back to Sir I. Newton. The article describes the formulation of the law, the ambiguity in the interpretation, as well as the problems with the inversion of measured gravitational fields.

Introduction

By gravimetry (Latin “gravis”) methods are identified, which can be used to measure the gravity field of the Earth. The determination of this potential field is of greater importance for Geodesy, Geophysics, and Geotechnics. In particular in Geophysics and Geodynamics, gravity is used to investigate the Earth's interior and its dynamic processes. Furthermore precise balances and other technical equipment need gravity data for their calibration.

The main objective of gravity/gravimetry is the determination of the Earth's gravity field and of other celestial bodies (e.g., the Earth's moon). The gravity field and its gravity gradients are measured as a function of position and time on, below, and above the Earth's surface, e.g., by gravity meters on ships, in boreholes, or on board of aircrafts and satellites: CHAMP, GRACE, GOCE, and GRACE-FO mission (refer among many others to Dahle et al. 2014).

In the seventeenth and eighteenth century, scientific interest and first measurements have been caused by the understanding and development of the Physics of deformable and rigid bodies. At that time determinations of position (distances) and time became accurate enough to enable gravity measurements. Later, after scientists discovered the position dependency of gravity, it has been used to determine the figure of the Earth – then until today. Developments of the gravity method were always correlated with the interaction of technical possibilities and scientific objectives in Physics (Geophysics) and land surveying (later then Geodesy) because geodetic surveying and geophysical exploration became a strong influence on growing societies (e.g., Torge 1989). Today the gravity field and its variations – measured by satellites with very high and unexpected accuracy – are closely related with the distribution and transport of masses in the Earth's system: the ocean circulation, changes of ground-water level and solid Earth moisture, melting of continental ice sheets, river runoff, changes of sea level, and mass flows in the Earth lithosphere and mantle, all of this causes transport and redistribution of masses. Using innovative and extremely

precise gravity, sensor systems dedicate gravity field to observe the implication of these processes. Even in the investigation of other celestial bodies, gravity gains in importance: already in the 1970s, the “Lunar surface gravity meter” was deployed at the Apollo 17 ALSEP site (Talwani 2003). Later NASA’s “Gravity Recovery and Interior Laboratory (GRAIL) Mission” measured the moon’s gravity field in unprecedented detail (e.g., Zuber et al. 2013; Wimsberger et al. 2018). Gravity field models of other celestial bodies (Mars and Venus) are available at the web page of the “International Centre for Global Earth Models – ICGEM” (<http://icgem.gfz-potsdam.de/home>) for download and visualization.

In the following chapters, all values of parameters of the Earth’s gravity field are related to the World Geodetic System 1984 (WGS 84).

Potential Function

It is accepted that the force $\mathbf{F}$ of a mass point m , which is influenced by a timely constant gravity acceleration $\mathbf{g}$, can be expressed by

$$\mathbf{F} = m\mathbf{g}.$$

To move this mass along a path C with path elements $d\mathbf{r}$ from a space point P_1 to a second point P_2 , an energy U_{12} has to be applied:

$$U_{12} = - \int_{P_1}^{P_2} \mathbf{F} \cdot d\mathbf{r} = -m \int_{P_1}^{P_2} \mathbf{g} \cdot d\mathbf{r} \quad (1)$$

There is no loss of energy, and we call U_{12} independent from its path and only dependent from start and end point P_1 respective P_2 . Equation (1) shows that only the difference of potential energy at points P_1 and P_2 can be calculated. The force $\mathbf{F}$ can be derived from the potential energy as

$$\mathbf{F} = -\text{grad } U = -\nabla U \quad (2)$$

$\mathbf{F}$ is a potential field. Equation (2) holds even if we add a constant U_0 . This constant will be selected in a way that potential energy disappears in the infinite. In this case $U(P)$ defines the energy in the field of gravity acceleration which has to be applied to m to move it from point P to the infinite:

$$U(P) = - \int_P^{\infty} \mathbf{F} \cdot d\mathbf{r}.$$

In Geophysics and Geodesy, the potential energy U is replaced by the potential (potential function):

$$V = -U/m. \quad (3)$$

This is the negative potential energy per mass unit and with (2) one has

$$\mathbf{g} = \nabla V.$$

Therefore, a gravity field can be described in entire space by a single function V . The potential function fulfills the Poisson differential equation:

$$\Delta V = -4\pi f \rho \quad (4)$$

with $f = (6.67430 \pm 0.00015) \cdot 10^{-11} \text{ m}^3/\text{kg s}^2$ (gravitational constant; see below)

ρ = mass density

The Poisson equation forms the base of potential theory and is an elliptic differential equation. If space is mass-free ($\rho = 0$), the Laplace equation holds in Cartesian coordinates:

$$\Delta V = \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0 \quad (5)$$

It became the most universal differential equation in the physical sciences because of the wide range of phenomena that is described by it. There exists a multitude of solutions of this differential equation which are not always potential functions. For both differential equations, hold the following definition:

A space function and its second derivatives which are continuous and bounded in a region where defined are called harmonic functions if they fulfill the LAPLACE and – in the interior of a mass filled space – the POISSON differential equation.

Newton’s Law and Newtonian Potential

In 1687 Sir Isaac Newton published his famous treatise *Philosophiae Naturalis Principia Mathematica* which contains Newton’s law of gravitational attraction:

The magnitude of a gravitational force between two masses is proportional to each mass and inversely proportional to the square of their distance.

In a Cartesian coordinate system, a mass m_0 is centered at point $P_0(x'y'z')$ and at point $P(xyz)$ a mass m . Then a force acts on mass m_0 (Fig. 1):

$$\mathbf{F}(P) = -f \frac{mm_0}{R^2} \mathbf{e}_R \quad (6)$$

with

Gravity Method, Principles, Fig. 1 Masses m_0 and m experience a gravitational force which follows Newton's law: it is proportional to m_0 and m and $1/r^2$. By convention the unit vector $\mathbf{e}_R$ is directed from the gravitational source point (P) to the "observation" point P_0 which is located at the mass m_0

$\mathbf{R} = \overrightarrow{P_0P}$ (vector which points from P_0 to P)

$\mathbf{e}_R = \mathbf{R}/R$ (unit vector) of $\mathbf{R}$

$R = [(x - x')^2 + (y - y')^2 + (z - z')^2]^{1/2}$ (norm of vector $\mathbf{R}$)

The gravity acceleration $\mathbf{g}$ which is caused by mass m is

$$\mathbf{g}(P) = \frac{\mathbf{F}(P)}{m_0} = f \frac{m}{R^2} \mathbf{e}_R \quad (7)$$

In Cartesian coordinates one can write

$$\mathbf{g}(P) = -\frac{f m}{R^3} [(x - x')\mathbf{i} + (y - y')\mathbf{j} + (z - z')\mathbf{k}] \quad (8)$$

$\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are components of the unit vector in a coordinate system.

At the Earth's surface, gravity acceleration is approximately $g = 9.81 \text{ m/s}^2$. The potential V is a scalar and an additive quantity. Therefore, the gravity potential of n point masses can be written as

$$V(P) = f \sum_{i=1}^n \frac{m_i}{R_i}, \text{ with } R_i \text{ (spaces of the } n \text{ points } P)$$

At the point masses, $V(P)$ is not defined due to $R_i = 0$. However, except for these singular points, the Laplace equation holds.

For a mass continuum, we obtain from Eq. (6) the Earth's gravitation by Newton's law of gravitation:

$$\mathbf{b}(\mathbf{r}) = f \iiint_{\text{Earth}} \frac{\mathbf{r}' - \mathbf{r}}{|\mathbf{r}' - \mathbf{r}|^3} dm$$

where $\mathbf{r}'$ and $\mathbf{r}$ are the geocentric position vectors of a mass element dm and the attracted point P (unit mass = 1) and

Gravity Method, Principles, Fig. 2 To illustrate the calculation of gravity effects in a point P at the Earth's surface, which depend on the attraction of celestial masses (sun and moon) and the centrifugal acceleration (δ = pol distance, ω_E = angular velocity vector)

$|\mathbf{r}' - \mathbf{r}| = R$. The mass element dm can be expressed by the volume density $\rho = \rho(\mathbf{r}')$ and the volume element $dm = \rho dv$:

$$\mathbf{b} = \text{grad } V$$

For the Earth's gravitational potential with v = volume of the Earth, we have

$$V(\mathbf{r}) = f \iiint_{\text{Earth}} \frac{\rho(\mathbf{r}')}{|\mathbf{r}' - \mathbf{r}|} dv \quad (9)$$

Besides the attraction of the Earth at points P, generally all cosmologic masses contribute to this attraction. However, in most cases only the influence of sun and moon is considered. The entire gravity attraction can be obtained by

$$\nabla V(P) = \mathbf{a}_E(P) + \mathbf{a}_C(P) \quad (10)$$

$\mathbf{a}_E$ (attraction of Earth)

$\mathbf{a}_C$ (attraction of cosmological masses)

$\mathbf{a}_E$ causes time-dependent deformations of Earth by tidal effects, and each mass point P is dislocated by a very small value R_D . Each mass point is influenced by the rotation of Earth, and its angular velocity is given by $\omega_E = 7.292115 \cdot 10^{-5} \text{ rad/s}$.

In an Earth-centered coordinate system, the position vector $\mathbf{R}_P$ which points to point P is given by (refer also to Fig. 2)

$$\mathbf{R}_P = \mathbf{R}_1 + \mathbf{R}_D$$

Then, the gravity vector $\mathbf{g}(P)$ can be calculated by $\mathbf{g}(P) = \nabla V(P) - \ddot{\mathbf{R}}_P$. It holds

$$\dot{\mathbf{R}}_P = \dot{\mathbf{R}}_D + \dot{\mathbf{R}}_1 = \dot{\mathbf{R}}_D + (\omega_E \times \mathbf{R}_1)$$

and

$$\ddot{\mathbf{R}}_P = \ddot{\mathbf{R}}_D + (\omega_E \times (\omega_E \times \mathbf{R}_1))$$

disregarding the small changes of rotational velocity $\dot{\omega}_E$. The gravity vector can be written as:

$$\mathbf{g}(P) = \mathbf{a}_E(P) + \mathbf{a}_C(P) - \ddot{\mathbf{R}}_D + (\omega_E \times (\omega_E \times \mathbf{R}_1)) \quad (11)$$

The first term represents the attraction of Earth, the latter the centrifugal acceleration which is caused by Earth rotation.

The middle terms $\mathbf{a}_C(P) - \ddot{\mathbf{R}}_D$ display the time-dependent part of Earth tides. For precise gravity field determinations, it must be observed and eliminated from the observations. The tidal correction which is caused by sun and moon never exceeds $0.3 \times 10^{-5} \text{ m/s}^2$.

For the centrifugal acceleration $\mathbf{a}_z$, we can write

$$\begin{aligned} \mathbf{a}_z &= (\omega_E \times \mathbf{R}_1) \times \omega_E = \omega_E^2 \mathbf{R}_1 - (\omega_E^2 \cdot \mathbf{R}_1) \omega_E \\ &= \omega_E^2 \cdot \mathbf{R}_\perp \end{aligned} \quad (12)$$

with

$\mathbf{R}_\perp$ = to the Earth's rotation axis perpendicularly oriented-component of $\mathbf{R}_1$.

Because $\mathbf{R}_\perp = 1/2 \nabla R_\perp^2$, also $\mathbf{a}_z$ is a gradient field:

$$\mathbf{a}_z = \nabla Z \text{ and } Z = 1/2 \omega_E^2 R_\perp^2$$

Z is called the potential of the centrifugal acceleration, and one obtains for the complete potential of the Earth with (9):

$$W = V + Z \text{ and } \mathbf{g} = \nabla W. \quad (13)$$

Anomalies

From Eq. (13) the normal gravity field (γ_0) can be deduced from a "normal Earth body" (among others, e.g., Heiskanen

and Moritz 1967; Torge 1989; Blakely 1995). Geodesists and Geophysicists agreed that the "normal gravity" is defined at an equipotential surface which is part of a spheroidal surface that bounds a rotating, uniformly dense Earth. Due to the gravity (attraction) and rotation forces, such a spheroid has a very comparable shape to an ellipse of rotation. Consequently, it is called a reference ellipsoid: in the WGS84 geodetic system, the flattening of the ellipsoid is $f = 1/298.257223563$. Readers wishing additional information are referred to publications by Li and Götze (2001) and Hackney and Featherstone (2003).

Local variations in altitudes and densities of crust and mantle and geological formations cause variations in the Earth's gravitational field, known as gravitational anomalies. Some of these anomalies can be very extensive and cause even bulges in sea level. The study of these anomalies forms the basis of the gravity discipline in Geophysics (see *Gravity, Data to Anomalies*). The gravity field which forms these anomalies is measured with extremely sensitive gravimeters and today detected also with gradiometers (Götze and Pail 2018; Difrancesco 2007). The effect of topography and other known factors (see below) is subtracted from the observations. Such techniques are used by Geophysicists to explore oil and mineral deposits and global structures. Denser rocks (often containing mineral ores) cause higher than normal local gravitational fields on the Earth's surface; less dense sedimentary rocks cause negative anomalies. The separation of gravity anomalies which are caused by local density variations of rocks and geological formations implicates corrections of the observed gravity. It was suggested by Blakely (1995) to describe these corrections as contributions to the field which was measured:

Observed gravity = attraction of the reference ellipsoid (normal gravity)
 +effect of heights above geoid (FREE – AIR correction),
 +effect of topographic masses above geoid (BOUGUER and TOPOGRAPHIC correction),
 +effect of time – dependent variations (TIDAL correction),
 +effect of moving platforms (EOTVOS corrections),
 +effect of masses that support loads (ISOSTATIC corrections),
 +effect of both known and unknown crust/mantle density variations (GEOLOGY).

It is the goal of each interpretation to isolate the effect of geological bodies from all other terms. We have to consider that the magnitude of this effect is relatively small if compared with the value of normal gravity:

Normal gravity approximately is 9.81 m/s^2 and

Gravity effects of "Geology" approximately are $10^{-5} \text{ m/s}^2 - 10^{-3} \text{ m/s}^2$

This is less than 0.01% of the observed gravity field magnitude. In Geophysics one distinguishes the standard anomalies: free air, Bouguer and Isostatic, explained in the entry *Gravity Data to Anomalies* in this encyclopedia.

The interpretation of the physical meaning of Bouguer anomalies is an old problem associated with various and often different assumptions and simplifications introduced

for the calculation of height and mass correction terms. It is also related to the purpose the anomaly is used for in Geodesy or Geophysics. However, one has to emphasize that Bouguer anomalies do not represent the gravity effect of anomalous density at a horizontal reference level. A comprehensive, modern presentation of all problems related to the normal gravity correction has been summarized by Pašteka et al. (2017) in order to eliminate any misunderstandings.

Ambiguity and Principle of Equivalence

The interpretation of gravity anomalies is not unique, and boundary conditions are always required, mainly from other geophysical disciplines and/or geology. It can be easily shown by modeling that for a given anomaly and a given density contrast, a wide range of possible interpretations can be made: at various depths, based upon different geometrical shapes. Nor does the method of interpretation by the gravity field gradients allow us to make a unique interpretation or to distinguish deep from shallow anomalies as has been claimed: it has been shown that we cannot escape the ambiguity by using second derivative quantities (gradients) or curvature and that, in fact, gravity and its derivatives are related by a corollary of Green's theorem. This theorem provides an analytical proof of ambiguity not only for the case of gravity data but also for magnetic data as well (e.g., Skeels 1947).

The Inversion Problem

The ambiguity of the inverse problem of gravimetry originates from potential theory. It is related with the computation of density functions from the observed gravity field. Density functions yield information of location, shape, and densities of causing masses. The computation leads to an integral equation, for which no unique solution exists. For a gravity anomaly generated by a particular mass distribution, infinitely many equivalent disturbing masses can be constructed at depths above the maximum depth of a disturbing body (Fig. 3). However, the total mass of the disturbing body (surface integral of the gravity anomaly, the lateral position of its mass center, and the corresponding coating on the surface of the Earth (special case of an equivalent disturbing mass) can be determined uniquely. If certain conditions are met, limiting values of maximal depth, density (difference), thickness, and lateral extension of the disturbing body can be found. The necessary additional independent information (constraints) is taken from other geophysical methods, geological, and/or petrological investigations.

In practical solutions of inversion problems, the *direct problem* of gravity appears, i.e., the computation of gravitational effects caused by particular mass contributions given in terms of location, shape, and density. In this case a unique

Gravity Method, Principles, Fig. 3 Gravitational potential (V), vertical gravity component, and derivatives of gravity over a homogeneous sphere with a depth of 5 km, a radius of 1 km, a density contrast of 1 kg/m^3 , and the equivalent masses between surface and maximum depth (after Torge 1989)

solution is always possible by application of the law of gravitation, Eq. (9).

Units and Gravitational Constant

Gravity is measured in ms^{-2} which is the standard unit in the “Système International d’Unités” (SI units are used in Physics since 1972). The six independent components of the gravity gradients are measured in s^{-2} . For many applications of gravity field, the following units are useful:

$$\begin{aligned} 1 \text{ nm s}^{-2} &= 10^{-9} \text{ m s}^{-2} \text{ or} \\ 1 \mu\text{m s}^{-2} &= 10^{-6} \text{ m s}^{-2}. \end{aligned}$$

Also the older cgm – units are still used in Geophysics and Geodesy:

$$\begin{aligned} 1 \text{ Gal} &= 1 \text{ cm s}^{-2} \\ 1 \text{ mGal} &= 10^{-5} \text{ m s}^{-2} \text{ or} \\ 1 \mu\text{Gal} &= 10^{-8} \text{ m s}^{-2}. \end{aligned}$$

“Gal” was (is) used in honor of the famous Renaissance Physicist Galileo Galilei (1564–1642). Although these older cgm units are no longer admitted, in Applied Geophysics they are still in use, together with “gravity units” ($\text{g.u.} = 1 \mu\text{m}^{-2}$).

Measurements and refinements of the gravitational constant have progressed since the time of Newton. However, up to now, laboratory experiments and physical research have not rendered a significant or generally accepted proof of $\dot{f} \neq 0$. The actual, recently published value (CODATA 2019) of the

constant is $f = 6.674\,30 \times 10^{-11} \text{ m}^3/\text{kg s}^2$, with a standard uncertainty of $\pm 0.00015 \times 10^{-11} \text{ m}^3/\text{kg s}^2$ and a relative standard uncertainty of 0.2×10^{-5} by the Committee on Data of the International Council for Science.

Summary

This contribution describes the principles of the gravity method which was developed by Sir Isaac Newton in the seventeenth century and holds until today. The theory bases on the definition of a potential function which replaces potential energy. A space function and its second derivatives which are continuous and bounded in a region where defined are called harmonic functions if they fulfill the Laplace and – in the interior of a mass filled space – the Poisson differential equation. A normal gravity field can be deduced from a “normal Earth body,” and Geodesists and Geophysicists agreed that a “normal gravity” is defined at an equipotential surface which is part of a spheroidal surface that bounds a rotating, uniformly dense Earth. Due to the gravity (attraction) and rotation forces, such a spheroid has a very comparable shape to an ellipse of rotation. Consequently, it is called a reference ellipsoid. Local variations in altitudes and densities of the Earth’s crust and mantle and geological formations cause variations in the Earth’s gravitational field, known as gravitational anomalies. In Geophysics elevation is used in all the corrections including the height correction and the complete Bouguer correction. In addition one should correct observed gravity for the geoid shape. The gravity effects due to the geoid undulations (N) are called the “indirect effects.” Any gravity field interpretation is effected by the ambiguity of the inverse problem of gravimetry which originates from potential theory; it is related with the computation of density functions from the observed gravity field.

Gravity Method, Satellite

G. Balmino

Centre National d’Etudes Spatiales, Toulouse, France

Definition

The determination of the gravitational potential of the Earth by space methods consists in computing the spherical harmonic coefficients of a truncated representation of the

external potential, from observations of artificial satellite orbits close enough to the Earth's surface, from ground stations or from other satellites (generally of higher altitudes), and also from special measurements made onboard a satellite.

Introduction

The knowledge of the gravity field of the Earth and of an associated reference surface of the altitudes (the geoid) is necessary for geodesy, for improving theories of the physics of our planet interior and surface, including various mass transfer mechanisms, and for modeling the ocean circulation in absolute. This knowledge comes from several observing techniques; on the global scale, it mostly benefited from the observation of artificial satellite orbits and has been improved over decades. The current approach, based on the accumulation of information from a large number of satellites, one being observed at a time, reached its limits around year 2000. Dramatic improvements now come from newly implemented space techniques already proposed in the 1970s and rendered possible thanks to technological progress; they were exemplified in the 2000 and 2010 decades by the CHAMP, GRACE then GRACE-FO, and GOCE missions which are realizations of the satellite-to-satellite (SST) tracking principles (in the high-low and low-low modes), of satellite gradiometry, together with the systematic use of micro-accelerometry to measure the surface forces which are a source of uncertainty in gravity field mapping from satellites.

Geodesy, Gravity Field, and Scientific Applications: Why?

Geodesy is a science which major goal is to define and study the shape of the Earth, its deformations (from relative movements of points on its surface), and its gravitational field (or its gravity field if one includes the rotational effects). It is an old discipline which acquired its fame in the eighteenth century when French scientists went measuring arcs of meridians, in Lapland and Peru, in order to determine whether the Earth was flattened at the poles or at the equator. Two hundred years later, the use of artificial satellites yielded a global and continuous view of our planet, and geodesy, too, benefited from this revolution. It became a science at the crossroads of others; for instance it is used daily for navigating satellites with high precision for oceanography, geophysics, and a variety of societal applications. In the mid-1960s first global models of the Earth's gravity field from satellites initiated a revolution in geophysics from space; about 40 years later we are witnessing a new era which sees the deciphering of our planet's gravity with unprecedented resolution and accuracy.

For a better understanding of both surface and deep phenomena which are related to the interior structure of the Earth and its temporal evolution, for studying the dynamics of the oceans and their interaction with meteorological and climate changes, for modeling the ice caps-oceans-continent relationships and for predicting the long-term evolution of the mean sea level, and also for unifying vertical reference systems and for the precise determination of satellite orbits in space, it is mandatory to know our planet gravity field to ever-increasing resolution and precision – including its temporal variations induced by the aforementioned phenomena. Details are provided by Jekeli (*this encyclopedia*); we limit ourselves to qualitative arguments on the dual role of the gravity field in Earth sciences.

On the one hand, by comparing the real field with the field of an idealized body (e.g., an ellipsoid in hydrostatic equilibrium), one defines gravity anomalies which characterize deviations from a state of internal equilibrium (i.e., nonradial density variations), which constitutes one method of sounding our planet's interior. The magnitude of gravity anomalies is in the range $-1,000/+1,000$ mgals ($1 \text{ mgal} = 10^{-5} \text{ ms}^{-2}$). As a matter of fact, this is one of four ways of “looking” inside, the other three being seismology, magnetic field studies, and the analysis of the Earth's rotation. However the gravity analysis approach is unique in providing direct information on the density field (although this is integrated and cannot be univocally inverted). When one strips the Earth from its topographic blocks (with assumed or known density), one is left with residual gravity anomalies which magnitude is not much different from the magnitude of the original ones; this exemplifies the phenomenon of isostasy, which is the concept of mechanisms of support of the topographic masses. Therefore the residual field mirrors mass excesses or deficits in depth which inform us on the lateral structure of the lithosphere and upper mantle. A significant part of this information is to-day provided by seismology and by tomographic analysis, but still suffers from uncertainties due to hypothesis on which such inversions are based. The combination of both types of data (seismic velocities and gravity anomalies) is a powerful tool to get a better picture of the interior and to make progress in the understanding of several phenomena, for instance, the accumulation of stresses and triggering of earthquakes.

On the other hand, a surface which is intimately related to gravity, the geoid, is used as the reference for defining and measuring the altitudes on the continents but also under the oceans or over the ice caps. The geoid is a particular equipotential surface of the gravity potential (the sum of the gravitational and centrifugal potentials) which may be viewed, in oceanic areas, as the surface of an ocean at rest. The Earth's rotation being sufficiently well-known and its effects being smooth at the surface (they essentially decrease with increasing latitudes), the irregularities of the geoid (in the ± 100 m range, as measured with respect to an ellipsoid of revolution

which approximates the Earth's shape) characterize the density field variations in a way similar to the gravity anomalies. In addition, on the topographic surface, water naturally flows along the geoid (or other equipotential) slope; over the oceans, seawater circulates (under the forcings of winds and density-salinity fluctuations), and these movements (different from the vertical displacements of water due to tides) and associated amounts of transported water (and heat, chemicals, nutrients, etc.) can be quantified with respect to the geoid: these are the ocean currents. One distinguishes between the mean and the variable parts of the circulation: the latter can nowadays be monitored by satellite altimetry, whereas the former (which is needed in the modeling of the climate by quantifying the long-term absolute transports of heat – especially in the shallow parts of the oceans) requires the precise knowledge of the geoid; the difference between the mean sea surface and the geoid is the ocean dynamic topography; the mean sea surface itself can be deduced from long series of altimeter measurements, but it is demanded that the geoid be independently determined.

For both solid Earth physics and oceanography, the requirements to-day are (at least) for a 100 km resolution geoid (and gravity field) with a cumulated error – i.e., up to that resolution, of 1 cm (and 1 mgal) or better. Clearly the classical domains of geodesy (unification of vertical reference systems, inertial navigation, accurate satellite orbits for monitoring the Earth's deformations, the sea surface, the Earth's kinematics, etc.) will greatly benefit from such knowledge.

In addition to this, there is a growing interest, in relationship with environmental studies and prediction capabilities, in measuring the time variations of the gravity field (see Cazenave, *this encyclopedia*). Some of them (e.g., the oceanic and solid tides) are deduced from the measurements or modeling of phenomena which are responsible for them, with satisfactory precision and resolution – or close to be satisfactory. On the contrary others can only be determined from direct observations, from which the responsible phenomena are then modeled. These are the postglacial rebound of the lithosphere (therefore of the planet surface); the variations of the ice caps, of the sea level, and of the large continental aquifers; and the distribution of precipitations (rain, snow), the soil moisture, and the evapotranspiration, that is, the water cycle in general.

Classical Ways of Measuring the Earth's Gravity Field

Up to a few years ago, three types of information have been used to describe or model, at local, regional, or/and global scales, the Earth's gravitational potential and various functionals:

- Surface measurements of gravity, on land, at sea (with ships and submarines), and by plane (more recently).

This is the oldest approach, much improved along its history. The measurements are often reduced to gravity anomalies and then gridded and made available at a variable resolution which depends on the area, on the actual density of observations, and also on restrictions still exerted by many countries for protecting national economic (sometimes military) interests. The resolution of such grids varies from a few to hundreds of kilometers, and the precision ranges from about 1 to 10 milligals – the accuracy may be worse due to systematic errors in many data sets (such as the old marine surveys). The data are archived at world level, mainly at the National Geospatial-Intelligence Agency (NGA) in the USA, and at the Bureau Gravimétrique International (BGI) in France. Airborne measurements are slowly expanding, but the precision at ground level (after downward continuation) is still insufficient. More information on gravimetry is provided in cross-references.

- The classical analysis of satellite orbit perturbations: since the 1960s a few groups in the world have determined global gravity field models from the inversion (via the law of the dynamics) of satellite orbit perturbations – which reflect the forces acting on a satellite. This has also been the current and very successful way of determining the gravity field of other solar system bodies (Nerem 1995). Most used Earth's satellites were indeed never designed for such purpose: the space geodesists simply took benefit of the more or less accurate measurements made from ground stations on these satellites for orbit knowledge. Various techniques were exploited, essentially the Doppler effect on the signal transmitted from a stable oscillator onboard a spacecraft to ground stations – or the reverse (case of the DORIS system), and roundtrip ground to satellite distances measured by laser systems – and optical determination of the satellite positions on the star background was also used at the beginning. The main limitations of these models come from the altitude of the observed satellites (due to the quasi-exponential decay of the perturbations with altitude), from the observation coverage (limited by the ground station networks and pass duration), and from uncertainties in modeling the surface forces (atmospheric drag, solar radiation pressure, and Earth albedo). If the data coverage has improved for some satellites thanks to the development of denser station networks (e.g., the DORIS system), or by tracking satellites from “above,” that is, by the GPS (Global Positioning System) constellation since the 1980s and presently by most GNSS (Global Navigation Satellite System) spacecraft, the other limitations remain and prevent from making significant progress. Solutions derived from satellite only data up to year ~2000 covered spatial scales from 500 to 40,000 km, but they were reliable (say at the centimeter level on the geoid knowledge) only down to a resolution of about 1000–1500 km. That is why they have

been – and are still combined with surface gravimetric measurements and altimetric data (see below) which bring higher resolution if not precision – depending on the area; such combined models globally reach 50 km resolution. The same strategy was applied with a much better satellite solution based on GRACE mission data and yielded the EGM 2008 model which has, in principle, a 10 km resolution though it represents the field with such details solely over areas with enough surface data. A detailed account of global gravity modeling history, techniques, and satellites used so far is given by Pavlis (*this encyclopedia*). In Sect. 5 we give an overview of the mathematical methods used to retrieve gravity field information from satellite dynamics.

- Satellite altimetry over the oceans: this is a space technique by which one measures (by radar or laser) the distance between a spacecraft and the sea surface, provided that the spacecraft position is known with sufficient precision it provides the sea surface which time average is close to the geoid but differs from it, the difference being the ocean dynamic topography (up to about 1 m in areas of strong currents such as the Gulf Stream, the Arctic Circum-polar Current, the Kuro-Shio). For several applications in marine geodesy and geophysics, it is sufficient to correct for the mean circulation with the present (approximate) models, though coastal currents, uncertainties in tidal models, and larger error measurements close to the shore limit the usage of the information to the offshore and open ocean areas. Such restriction being understood, satellite altimetry data have had an important contribution to global Earth's gravity models in increasing their resolution over the oceans – but without providing the true geoid.

New Satellite Missions

Basic principles were found years ago; technological advances have allowed for their implementation.

To get rid of the limitations of past systems, any new satellite approach should satisfy as many of the following criteria as possible, quasi-polar orbit (for the coverage), 3-D uninterrupted measurements (for recovering the gravity signals with an isotropic error), and mean altitude as low as possible (for higher resolution), counteract the effects of signal attenuation with altitude by a differencing measurement method, and isolate the gravitational signals by measuring and/or compensating the surface forces (which involves ultra-sensitive accelerometers). The missions launched during the 2000–2020 decades satisfy more or less these criteria. Working at low altitude is the constraint which has received most attention and all missions fly at or below 450 km (compared to the altitudes of satellites used so far: 800 km or larger). Surface forces are measured by micro-accelerometers (and even compensated in the case of the gradiometric mission). The other

criteria have been considered differently according to the type of mission and the used technology.

The first dedicated satellite mission, launched in 2000, was CHAMP (Challenging Mini-Satellite Payload for Geophysical Research and Application) (Reigber et al. 1996); its two main objectives were the mapping of the magnetic field and of the gravity field of the Earth. It was developed by Germany, with French contributions (magnetometers and a triaxial electrostatic micro-accelerometer) and the provision of a GPS receiver by the USA; this is one realization of the SST approach in the high-low mode (with a lower segment altitude of 450 km, decreasing to about 300 km toward the end of mission in 2010), which resulted in the first significant leap in gravity modeling precision.

CHAMP appears as the precursor of the second gravity mission GRACE (Gravity Recovery and Climate Experiment), which is a USA mission (JPL 1998) conducted in cooperation with Germany and launched in March 2002. It consisted in flying two satellites separated by about 200 km from each other, on the same mean polar orbit; the satellites are each tracked by the GPS (like CHAMP) and besides measure their relative distance and velocity with a micro-metric accuracy – this observable (of the low-low SST type) may be viewed as an extremely fine measurement of the gravitational potential difference at the satellites. Each spacecraft was equipped with a micro-accelerometer (of a class superior to the CHAMP one). The mission exceeded its designed lifetime (like CHAMP): designed for a 5-year duration, it operated until October 2017. Besides improving our knowledge of the mean gravity field (by more than one order of magnitude), it brought a wealth of information on the seasonal and inter-annual time variations of the gravity field, especially those related to the hydrological cycle and ice cap volume changes. Due to the success of this mission, right from its first years, it was so obvious that monitoring the Earth's gravity time changes was becoming an essential part of the Earth's observing system and that a follow on mission was studied and decided: GRACE-FO, a partnership between NASA and the German Research Centre for Geosciences (GFZ), was launched in May 2018. GRACE-FO uses the same two-way microwave-ranging link as GRACE, which produces so called K-band measurements, and each spacecraft houses a micro-accelerometer. In addition, GRACE-FO employs laser ranging interferometry (LRI) as a technological experiment in preparation for future satellites, an instrument which improves the precision of the separation distance measurement by a factor of 20. Unfortunately the science phase of the mission was delayed until January 2019 due to an anomaly in a system component, and the mission is still plagued by a dysfunction of one of the accelerometers, which may affect the final precision which was envisaged.

The third type mission, which was selected in November 1999 as the first core mission of the Earth Explorer program of

ESA (European Space Agency), was GOCE (Gravity Field and Steady-State Ocean Circulation Explorer) (ESA 1999) launched in 2009. For the first time, a gradiometer was flown onboard a satellite on a very low altitude orbit (around 250 km) of 96.5 degree inclination, with drag-free control. It operated until October 2013 when he reentered the Earth's atmosphere. The gradiometer instrument consisted in six ultra-sensitive micro-accelerometers of a new class (capable of measuring accelerations of $5.10^{-13} \text{ ms}^{-2}$) and delivered gravity gradients (second derivatives of the gravitational potential) in spacecraft axes with an accuracy of a few milli-Eötvös ($1 \text{ E} = 10^{-9} \text{ s}^{-2}$) per $\text{Hz}^{1/2}$ in the 0.005–0.1 Hz measurement bandwidth. The satellite was also tracked by the GPS (and by ground laser stations, actually like CHAMP, GRACE, and GRACE-FO for control and safety), and the combination of these trajectory observations and of the gradiometer measurements has produced a global gravity model with a resolution of about 100 km with a total uncertainty of ~ 2 cm on the geoid.

Overview of Satellite Dynamics Methods

In the following we describe the main mathematical concepts and tools which are in common use in satellite geodesy, that is:

1. The representation of the gravitational potential
2. The solution of the dynamical problem, with two sub-parts:
 - The equations of motion and their solution
 - The equations, derived from the preceding ones, necessary for obtaining the trajectory and physical parameters at stake (i.e., for the inverse problem)
3. The setting up of the observation equations and their linearization in the inverse problem
4. The solution of the inverse problem

Some of the described material may be redundant with Pavlis (ibid).

The Representation of the Gravitational Potential

For most global studies, the potential of the Earth's attracted masses is usually modeled by a spherical harmonic series, written at each point P as:

$$U = \frac{GM}{r} + \sum_{l>0} \frac{GM}{r} \left(\frac{R}{r}\right)^l \sum_{m=-l}^{+l} K_{lm} P_{lm}(\sin \phi) e^{im\lambda} \quad (1)$$

with G , gravitational constant; M , mass of the Earth; K_{lm} , dimensionless harmonic coefficient of degree l and order m , and r , ϕ , λ , the spherical coordinates of the point P in a reference system fixed with respect to the Earth; the P_{lm} 's are the Legendre functions of the first kind (polynomials when $m = 0$) and, for computational stability reason, are

usually normalized (like the K_{lm} 's) – which we will assume in the following.

Alternatively, the sum of all terms of the same degree l can be written with real (normalized) coefficients and functions, in the form:

$$U_l = \frac{GM}{r} \left(\frac{R}{r}\right)^l \sum_{m=0}^{+l} \times (C_{lm} \cos m\lambda + S_{lm} \sin m\lambda) P_{lm}(\sin \phi) \quad (2)$$

The C_{l0} coefficients are called zonals, and the C_{lm} , S_{lm} ($m > 0$) are the tesseral harmonics with the sectorials ($l = m$) being a special sub-class. They may vary with time.

Practically the potential series is truncated at maximum degree L , i.e., $|m| \leq l \leq L$, and therefore $\dim \{K_{lm}\} = (L+1)^2$. L depends on the type of satellite orbits and data sensitivity.

When the K_{lm} are known, it is straightforward to compute any geodetic functional F , which is linear in these parameters:

$$F(U) = \sum_l f_l U_l \quad (3)$$

For instance:

- For the gravity anomaly field: $F = \Delta g$ and $f_l = (l-1)/r_E^2$
- For the geoid height: $F = N$ and $f_l = 1/\gamma(r_E, \phi)$

where r_E is the radius vector and $\gamma(r_E, \phi)$ is the normal gravity at the evaluation point on some adopted reference ellipsoid (E) approximating the shape of the geoid.

Variances and covariances can also be propagated to these functions from the covariance matrix (see 5.4) of the spherical harmonic coefficients (in particular the variances δC_{lm}^2 and δS_{lm}^2). Useful indicators of the precision of a model are the mean errors per degree on some given geodetic functional – usually the geoid and/or the gravity anomaly field, computed as:

$$\langle \delta F \rangle_l = f_l \left[\sum_{m=0}^l (\delta C_{lm}^2 + \delta S_{lm}^2) \right]^{1/2} \quad (4)$$

The Solution of the Dynamical Problem

The equations of motion are most often considered in rectangular coordinates with respect to a given reference system and written in a specific time scale. Although approximate analytical theories exist for describing the evolution of an orbit subject to disturbing forces (they are still in use for mission analysis and first-order scientific investigations), numerical integration is systematically used for higher precision. Forces acting on a satellite are not only of gravitational origin, and their complete modeling involves parameters, such as the K_{lm} coefficients, which determination requires to integrate other

systems of equations associated with those providing the trajectory.

Reference System and Time Scale

One makes choice of a time scale, such as the Geocentric Coordinate Time or the Terrestrial Time and of reference systems: one related to the Earth's surface (the International Terrestrial Reference Frame, or ITRF) and one fixed in space (the International Celestial Reference Frame, or ICRF) as defined by the International Astronomical Union and the International Association of Geodesy (IERS 2010). The K_{lm} coefficients are expressed in ITRF, and the equations of motion of a satellite are usually written in a system (EME2000) defined by the Earth mean equator and mean equinox of epoch J2000 (January 1, 2000 at 12 h) and fixed in ICRF. The transformation from ITRF to EME2000 involves all phenomena related to the rotational motion of Earth in space, that is, precession, nutation, sidereal time, and polar motion – of which parameters may be part of the unknowns in the inverse problem.

Equations of Motion

The spacecraft motion obeys the differential equations, in EME2000:

$$\ddot{\vec{r}} = \bar{\nabla}U + \bar{\nabla}U^* + \bar{\Gamma}_{SP} + \bar{\Gamma}_D + \bar{\Gamma}_{th} \quad (5)$$

with $\vec{r}(t_0) = \vec{r}_0$; $\dot{\vec{r}}(t_0) = \dot{\vec{r}}_0$ (initial conditions at beginning of a piece of trajectory – an arc).

In the above, U is the Earth's gravitational potential, U^* is the so-called third body gravitational potential, Γ_{SP} is the acceleration vector due to solar pressures (direct from the Sun, indirect, i.e., reflected by the Earth – known as the albedo effect) and to infrared pressure (radiated by the Earth considered as a black body), Γ_D is the acceleration due to drag from the atmosphere, and Γ_{th} designates the residual acceleration due to poorly known effects (e.g., thruster accelerations in the case of an orbit controlled spacecraft). U^* includes the Sun, the Moon, and planets.

For computing the surface accelerations Γ_{SP} and Γ_D , a so-called box-and-wing (macro) spacecraft model (with a few planar faces) is used (together with ad hoc physical coefficients), and one has also to use an attitude model. Alternatively, Γ_{SP} and Γ_D may be measured by very sensitive micro-accelerometers such as in the CHAMP, GRACE, GRACE-FO, and GOCE satellites. The Γ_{th} effects may be modeled via time series or as window (rectangular) functions at some specific epochs (for instance, the times of attitude maneuvers).

Integration of the Equations of Motion

This is the direct dynamical problem. Numerical integration is systematically used. Robust multi-step integrators, of the Adams, Adams-Moulton, or Cowell type, in normal form or

in summed form (which reduces the accumulation of round-off errors), are preferred. Such integrators have a starting phase and then a running phase with a predictor-corrector iterative scheme. One big advantage of such class of methods is that one can easily speed up the algorithm, by sometimes a dramatic factor in performing a pseudo-correction by which the full force function (right-hand side member of the dynamical equations) is replaced (after the first loop of the corrector part) by an approximation (e.g., the central term of the gravity field plus a few other important terms).

Variational Equations and Their Integration

The inverse dynamical problem consists in determining the physical models parameters (or a subset of them) from the observation of the satellite trajectory – by any means. It also implies the determination of the equations of motion initial conditions in a first step or simultaneously (usually by iteration).

As it is known, and as we describe it in the next subsection, this requires to obtain at each time t the partial (first) derivatives of the satellite state vector $(\vec{r}, \dot{\vec{r}})$ with respect to the components of the initial conditions vector (which we call $\bar{Z}$) and similarly with respect to the vector of all searched for physical parameters (which we call $\bar{P}$). This is achieved via the variational equations.

We rewrite the equations of motion as follows:

$$\begin{aligned} \ddot{\vec{r}} &= \bar{\gamma}(\vec{r}, \dot{\vec{r}}, t, \bar{P}) \\ \text{with } (\vec{r}, \dot{\vec{r}})_{t_0} &= \bar{Z} \end{aligned} \quad (6)$$

$\vec{r}$ and $\dot{\vec{r}}$ are functions of t , t_0 , $\bar{Z}$, and $\bar{P}$. Let w be any Z_j or P_k . Then:

$$\frac{\partial}{\partial w} \ddot{\vec{r}} = \frac{d^2}{dt^2} \left(\frac{\partial \vec{r}}{\partial w} \right) = \frac{\partial \bar{\gamma}}{\partial \vec{r}} \left(\frac{\partial \vec{r}}{\partial w} \right) + \frac{\partial \bar{\gamma}}{\partial \dot{\vec{r}}} \left(\frac{\partial \dot{\vec{r}}}{\partial w} \right) + \frac{\partial \bar{\gamma}}{\partial w} \quad (7)$$

We note that $\partial \dot{\vec{r}} / \partial w = d(\partial \vec{r} / \partial w) / dt$ and that the last term is present only if $w = P_k$.

Therefore any vector $\bar{g} = \partial \bar{\gamma} / \partial w$ is solution of the system of so-called variational equations:

$$\ddot{\bar{g}} = \frac{\partial \bar{\gamma}}{\partial \vec{r}} \bar{g} + \frac{\partial \bar{\gamma}}{\partial \dot{\vec{r}}} \dot{\bar{g}} + \left\{ \begin{array}{c} 0 \\ \partial \bar{\gamma} / \partial w \end{array} \right\}_{w=P_k}^{w=Z_j} \quad (8)$$

with

$$\begin{aligned} g_i(t_0) &= \dot{g}_i(t_0) = 0 \quad \forall i \quad \text{if } w = P_k, \\ &= \delta_{ij} \quad \text{if } w = Z_k, \end{aligned}$$

since this is nothing but the Jacobian $\left[\frac{D(r_i, \dot{r}_i)}{D(r_i(t_0), \dot{r}_i(t_0))} \right]_{t_0}$.

We have one such system for each parameter to be estimated, which could be very costly to integrate, but we note that:

$\partial \bar{\gamma} / \partial (\vec{r}, \dot{\vec{r}})$ is common to all systems ($\forall w$) and can be evaluated once (at convergence of the predictor-corrector

loop), at each stepsize in the course of the integration of the main system, these variational equations are linear (with coefficients function of time); therefore they can be economically integrated by quadrature or, more efficiently, by using solely the predictor part of the integrator (another approach uses the matrizant of the associated homogeneous system, followed by quadratures).

The Observation Equations for the Inverse Problem

The recovery of the gravity field model parameters is an inverse problem which consists, here, in deriving the gravity coefficients (K_{lm}) from a set of observation equations.

General Form of the Equations

Each measurement q of a functional f of the satellite position (or velocity) is of the type:

$$q = f(\bar{r}, \dot{\bar{r}}, t, \bar{Q}) \quad (9)$$

or

$$q = f(\bar{r}_1, \bar{r}_2, t_1, t_2, \bar{Q}) \quad (10)$$

Direct measurements of a gravity field functional (such as gravity gradients along one or several spacecraft axis) are of the form:

$$q = f(\bar{r}, \dot{\bar{r}}, t, \bar{P}) \quad (11)$$

In the above, $\bar{r}, \dot{\bar{r}}, \bar{r}_1, \bar{r}_2$ are usually functions of $\bar{Z}$ and $\bar{P}$, respectively, the initial condition (state) vector (often comprising other “fudge” parameters – e.g., empirical multiplying factors for the surface forces) and the dynamical parameter vector (of which the gravity field parameters is a subset). $\bar{Q}$ is a vector of geometric quantities (for instance, coordinates of observing stations) and/or other physical parameters (e.g., propagation delays in a medium).

The observation equations are usually nonlinear with respect to the unknown parameters. The classical approach is to linearize them around starting values:

$$\begin{aligned} \Delta q &= q^{\text{obs}} - q^{\text{comp}} \\ &= \frac{\partial q^{\text{comp}}}{\partial \bar{Z}} \Delta \bar{Z} + \frac{\partial q^{\text{comp}}}{\partial \bar{P}} \Delta \bar{P} + \frac{\partial q^{\text{comp}}}{\partial \bar{Q}} \Delta \bar{Q} \end{aligned} \quad (12)$$

with

$$\Delta \bar{Z} = \bar{Z} - \bar{Z}_0, \quad \Delta \bar{P} = \bar{P} - \bar{P}_0, \quad \Delta \bar{Q} = \bar{Q} - \bar{Q}_0$$

Partial derivatives are computed via the variational equations of the equations of motion of the satellite(s) when q is a distance, velocity... between an observing reference point

(a tracking station on Earth, another spacecraft – like in the Earth gravity mapping missions CHAMP, GRACE, GRACE-FO and GOCE), or are directly evaluated if q can be expressed as a simple function of the physical phenomena at stake at the satellite location, such as a gravity gradient in the case of a gradiometer sensing the gravitational potential (case of the GOCE mission).

More precisely, we have:

$$\begin{aligned} \frac{\partial q^{\text{comp}}}{\partial \bar{Q}} &= \frac{\partial f}{\partial \bar{Q}} \\ \frac{\partial q^{\text{comp}}}{\partial (\bar{Z}, \bar{P})} &= \frac{\partial f}{\partial \bar{r}} \frac{\partial \bar{r}}{\partial (\bar{Z}, \bar{P})} + \frac{\partial f}{\partial \dot{\bar{r}}} \frac{\partial \dot{\bar{r}}}{\partial (\bar{Z}, \bar{P})} \end{aligned} \quad (13)$$

(or $\partial f / \partial \bar{r}_1, \partial f / \partial \bar{r}_2$ if the observable involves two spacecraft with both orbits being adjusted simultaneously like in GRACE). In current observation systems, $\partial f / \partial \dot{\bar{r}}$ is not present: the only case would be a Doppler-type measurement, but this is always treated as a difference of ranges (between the beginning and the end of a given count time).

The quantities $\partial f / \partial \bar{Q}, \partial f / \partial \bar{r}$ are in principle easy to compute at the observation epoch although in practice one has to take account of the signal propagation duration, of small motions at the observing stations (solid and fluid tides loading effects, tectonic movements), of relativistic clock effects, etc.

Finally $\partial \bar{r} / \partial (\bar{Z}, \bar{P})$ is obtained by integration of the variational equations as described in the previous sub-section.

Example: Range Measurement Generic Observation Equation

All tracking observations of a satellite orbit involve one or several range values. Consequently, it is logical to construct a generic observation equation for a single range measurement between two points S_1, S_2 , being understood that the final equation for a real measurement is a combination of generic equations. Besides this allows an easy generalization to the case when the observing station is replaced by another spacecraft (a high altitude navigation satellite – e.g., from the GPS constellation or a co-orbiting satellite like in the GRACE mission). Therefore let us consider the case where S_2 is the satellite of interest and S_1 can be a station or another spacecraft.

Firstly propagation times must be taken into account by an iterative scheme which allows to refer the quantities to the true epochs (t_1 for S_1 and t_2 for S_2). Various corrections being properly applied the range $S_1 S_2$ then reduces to the geometric quantity:

$$r_{12} = \|\bar{r}_2 - \bar{r}_1\|$$

The observation equation is therefore:

$$r_{12}^{\text{obs}} - r_{12}^{\text{comp}} \approx dr_{12} = \hat{u}_{12} \cdot (d\bar{r}_2 - d\bar{r}_1) \quad (14)$$

with $\hat{u}_{12} = \bar{r}_{12} / r_{12}$ and

$$d\bar{r}_{n,i} = \sum_j \frac{\partial \bar{r}_{n,i}}{\partial (PInt_{n,i}^j)} \Delta(PInt_{n,i}^j) + \sum_k \frac{\partial \bar{r}_{n,i}}{\partial (PExt^k)} \Delta(PExt^k)$$

($n = 1, 2$).

The quantities with *comp* superscript are derived from the numerical integration of the equations of motion of the satellite (s), and the Jacobian matrices $\partial\{\dots\}/\partial\{P\dots\}$ are obtained from the integration of the variational equations; the i subscript refers to the i .th arc in a strategy where the ensemble of the processed data is split into several batches, and we have distinguished between internal (or inner) parameters (proper to the i .th arc) and external parameters (common to all arcs). For each batch of data, the inner parameters are solely solved for in an iterative process (because of significant nonlinearities); at the end all parameters are considered and the equations are solved in ensemble. The whole procedure may then be iterated.

The Solution of the Inverse Problem

The observation equations have been linearized, which yield the system:

$$Ax = b \quad (15)$$

where x is the vector of unknowns (of dimension N), A is a $M * N$ matrix (M is the number of observations and usually $M \gg N$), and b is the residual vector (of the Δq s). A weight matrix $\Pi(M * M)$ is associated to the observations; it is very often reduced to its diagonal part for practical reasons.

In some instances, the measurement bandwidth may be rather limited, and it is then necessary to filter the observation equations as precisely as possible. This has been the case of the GRACE K-band radar measurements and of the GOCE gradiometer data, for which very specific algorithms (due to the size of the problem) have been developed (Schuh 2003; Siemes 2008). This consists in applying a filtering matrix to both sides of the observation equation system. Another approach is to filter the spherical harmonic coefficients solution afterward (Kusche 2007) or to apply space domain filters to geodetic functions (Jekeli 1981; Han et al. 2005). Such procedures have to be applied to time variable gravity models (monthly or decadal solutions) derived from the GRACE and GRACE-FO missions.

These equations can be solved by least squares, usually by forming the normal equation system:

$$(A^T \Pi A)x = A^T \Pi b \quad (16)$$

from which x is computed; $N = A^T \Pi A$ is a $(N * N)$ matrix.

A regularizing procedure may be used when the observability and/or sufficient decorrelation of all parameters are not

guaranteed; in such a case N is replaced by $N + R$, where R is the regularizing matrix. This is usually necessary for the inner unknowns (initial orbital elements, empirical parameters, etc. which may not be fully determinable). For the physical parameters, R may be:

- Derived from an approximate physical law (e.g., Kaula's law for the gravitational harmonic coefficients – usually applied above a certain degree or for particular classes of coefficients such as the zonals)
- Obtained from a priori physical information

The covariance matrix of x is finally computed as:

$$\text{cov}(x) = \sigma_0^2 (N + R)^{-1} \quad (17)$$

where σ_0 is the variance of unit weight estimated from the system and residual vector.

Other methods (orthogonal decomposition – e.g., using QR factorization) may be used for computational accuracy reasons.

The computational cost of the formation of the normal system and of its solution is:

- Proportional to MN^2 for forming the normal equations or for an orthogonal decomposition
- Proportional to N^3 for obtaining the solution and the covariance matrix.

The first step is obviously the most demanding, and this aspect has always driven the strategy of research teams working on the determination of global gravity field models.

Progress Made: A Short Summary

Early in the Space Age, several research groups started working on the determination of the gravity field of the Earth. One of the first global models published was the Standard Earth I, by an American team at the Smithsonian Astrophysical Observatory (Lundquist and Veis 1966); it was a solution derived solely from analytical theory and satellite tracking (optical) data and complete to degree and order 8 (plus a few so-called resonant harmonics of higher degree and order). It was quickly followed by a combined solution (to degree-order 16) which was based on a little more satellite data and on mean surface gravity values (Gaposchkin and Lambeck 1970); this model was enriched some years later (Gaposchkin 1973). Meanwhile similar work (but based on numerical integration approach) had started at the NASA Goddard Space Flight Centre (GSFC) and in Europe where two groups (at CNES, the French Space Centre and at the Technical University in Munich) joined their efforts. This resulted in

two series of models: the GEM models on the American side (Lerch et al. 1972a, b) and the GRIM models on the European side (Balmino et al. 1976a, b). For several years these two series of models were improved: the GSFC team joined efforts with a group from the University of Texas at Austin, and the German side of the European alliance was transferred at the DGFI (Deutsches Geodatisches Forschungsinstitut) then at the GFZ (GeoForschungsZentrum). All teams involved in this domain produced many global models, each milestone being marked in general by a new satellite solution, followed by a combined model i.e., with the added (higher spatial frequency) contribution of surface gravimetry and ocean altimetry (see Pavlis, *ibid.*).

At the end of the twentieth century, models were limited (mostly in the precision of knowledge of their long and medium wavelength components) by the weaknesses of the satellite solutions; for instance the cumulated geoid error at degree 50 (400 km resolution) was still over 1 m. The revolution came with the advent of the new dedicated gravity missions: CHAMP quickly provided a gain of a factor 5 to 10 (depending on the resolution) to the models derived from it (and from other good past satellite data); GRACE allowed the

study of time variations (see Cazenave et al., this *encyclopedia*) and yielded mean (static) models which quality now reaches a centimeter error at degree 120; GOCE reached the expectation and complemented the GRACE-derived mean models in the higher spatial frequencies (up to degree 300). Due to the difficulty and importance of this type of research (which outputs require extremely thorough validation – by cross-verifications), many more groups have engaged in the processing of the new missions data, such as the Institute of Theoretical Geodesy at the University of Bonn which produced in 2010 the best gravity model from GRACE (Mayer-Gürr et al. 2010). Since then several institutes, especially in Europe, joined efforts to compute on a regular basis solutions from the new mission data, for both the mean Earth's gravity field and the time varying part. Figure 1 is an example of such results (Mayer-Gürr et al. 2015), obtained by the GOCO consortium composed of teams from the Technical Universities in Munich and Bonn (Germany), Graz (Austria), Bern (Switzerland), and the Space Research Institute in Austria. Other institutions, such as NASA-JPL (Jet Propulsion Lab., USA), the Centre for Space Research (Austin Univ., USA), GFZ (Germany), and GRGS (Groupe de Recherche de

Geodesie Spatiale, from the French Space Centre), continue to produce gravity models in fairly great number.

Global Earth's gravity field models computed since the beginning of the Space Age are now archived at GFZ, Germany, in the ICGEM service <http://icgem.gfz-potsdam.de/>, from which documentation, spherical harmonics sets of coefficients, and gridded values of geodetic functions can be retrieved. As an example, Table 1 lists some of the main satellite only solutions published since 1966.

Conclusion and Vision of the Future of Gravity Mapping from Satellite

New progress at global scale can only come from a space approach for this only can satisfy the scientific needs (homogeneous data, full coverage, higher resolution and precision) within reasonable time and cost.

From the results already obtained, which demonstrate that the new gravity missions have met the expected outcome, one can say that several of the objectives previously discussed have been reached. However, and like in other domains, new

requirements are emerging, encouraged by the findings of these missions: higher resolution and precision models and therefore measurements are to be needed.

If we restrict ourselves to the approach by satellite-to-satellite tracking or satellite gravity gradiometry, which are used in the new satellite missions of this decade, we may foresee improvements:

- On the precision of deciphering the time variations of the gravity field at shorter spatial scale, by exploiting further the co-orbiting satellites case like in GRACE; this will be done by performing inter-satellite range measurements by laser interferometry, a technique which is presently operated in GRACE-FO,
- on the resolution of the static field (mapping of finer lateral variations of gravity) by a satellite-borne gradiometer of enhanced sensitivity, such as a cold atom interferometry gradiometer (Douch et al. 2018).

Future progress may also be possible by revisiting the differential approaches, for instance, by differencing (or double differencing) relative velocity measurements, or

by flying two or more satellites in specific geometries (gravimetric “wheel,” pendulum configuration, etc.), or by flying simultaneously several GRACE-type constellations in order to gain on the temporal resolution.

But there comes a critical aspect, GRACE, and now GRACE-FO results have shown the great potential of such missions for environmental studies and call for the need to continue monitoring, without gap, the Earth’s gravity field variations (much like we continue monitoring the mean sea level by altimetry). GRACE lasted much longer than expected, but the following mission GRACE-FO was not yet ready to be launched in time in order to avoid a gap in the gravity model series. The missing months (it could have been years) were filled thanks to the availability of the SWARM satellite mission (several low altitude spacecraft tracked by the GPS and devoted to measuring the Earth’s magnetic field), though with a drastic reduction in the resolution of the recovered gravity variations (Meyer et al. 2019). The main issue is, and will be at each time a new gravity satellite system is flown, to decide on the follow-on mission as quickly as possible so as to avoid any discontinuity in the data series.

Definition

Gravity method	A geophysical technique based on measuring the variations in the Earth's gravity field at specific locations.
Gravity stations	Locations where gravity measurements are made.
Base gravity stations	Locations where absolute value of the Earth's gravity field is known.
Primary base	Gravity observation stations, which are made on stable platform and absolute value of the gravity field is known to a greater accuracy.
Secondary bases	Temporary bases established for a particular survey.
Closed loop	Bases that are connected in a loop for base loop correction.
Drift correction	Correction applied for nontidal variation of gravity, which is mainly dependent on the behavior of gravity meters with time.
EOTVOS correction	Correction applied to marine gravity data for the movement of ship.
	mGal; 1 mGal = 10^{-5} m/s ²
	μGal; 1 μGal = 10^{-8} m/s ²

Introduction

Gravity method in geophysics is employed to determine subsurface density distribution by measuring the variation of the Earth's gravity field. Measurements of gravity field are usually made on the Earth or ocean surface. The scale of investigations (accuracy and spatial distance of gravity measurements) depends on the type of geological problems being investigated. These vary from a few μGal to mGal of measurements accuracy, which is a few millionth of average Earth's gravity field (9.8 m/s^2) and station intervals of a few meters to a few kilometers. Based on applications, gravity survey can be broadly classified into the following three groups (Mishra 2011):

1. Regional gravity surveys: Station spacing is a few kilometers and survey accuracy is of about 1 mGal. It is generally used for tectonic and geodynamic studies.
2. Reconnaissance gravity surveys: Station spacing is a kilometer or so and survey accuracy is of 0.1–0.5 mGal. Such surveys are normally planned for delineating promising zones for hydrocarbon and mineral exploration and tectonic and lithological mapping.
3. Detailed gravity surveys: Mainly done to demarcate local geological structures favorable for mineral deposits, engineering applications, and groundwater studies. Survey accuracy is in the order of ~ 0.01 mGal and station interval is in the order of a few meters.

Measuring Equipment

Gravity Measurements

There are primarily three methods of measuring Earth's gravity field:

- (a) A method in which period of pendulum is used to find absolute value of gravity
- (b) Method based on measuring velocity of free-falling body in the vacuum chamber that also provides absolute value of gravity
- (c) Sensitive spring balance, in which a test mass is suspended through a spring and change in the spring length offers variation in the Earth's gravity

The spring balances are relative instruments; however, they are main source of gravity data recording. They measure the differences in the gravity field between two locations and one of them is a base station. The Worden gravimeter, the Scintrex, and the La Coste Romberg gravimeter are extensively employed gravimeters across the globe. Scintrex gravity meters are now only commercially available gravity meters, which have least count of $1 \mu\text{Gal}$. Similar kinds of gravity meters are also used on the ship; however, they are specially designed to take care of vertical and horizontal accelerations with gyroscopic adjustments. A detailed account of gravity measurements is described in several publications (Marson 2012; Niebauer 2015; Van Camp et al. 2017). These measurements are mainly of two kinds: absolute gravity and relative gravity measurements. Absolute measurements provide Earth's gravity values directly at any location whereas relative gravity observations offer gravity variations only.

Elevation and Position Measurements

Gravity field of the Earth increases as we move toward poles due to flattening and centrifugal force. The factor that affects the Earth's gravity field most is the distance from center of the

Earth (R). Therefore, the elevation of stations and its position should be precisely known for gravity surveys. There are several ways to know the position and elevation, but nowadays global positioning system (GPS) provides a best method of determining position and elevation by utilizing information from several orbiting satellites. Sometimes, when measurements are made in shadow regions, particularly in the forests, the GPS navigations are not very good. In such cases, theodolite, navigation based on maps, and elevation using pressure measurement devices are often used as per the requirements of survey accuracy. GPS measurements are improved by using them in differential GPS (DGPS) mode. The accuracy of a position obtained using DGPS mode is a few centimeters in horizontal and tens of centimeter in vertical. Correctness of determined height is dependent on the knowledge of geoid height in the survey area. DGPS navigation systems that provide position, speed, and heading information of ship are common now for shipborne gravity measurements.

Land Gravity Survey

Gravity survey often refers to the measurement of the Earth's gravity field along with the position and elevation of the observation point. Elevation effect is approximately $0.2\text{--}0.3 \text{ mGal/m}$ implying that an error of 1 m in elevation of the stations will affect the gravity measurement by about 0.2 mGal which is quite significant, especially when the accuracy of gravimeters is $0.01\text{--}0.001 \text{ mGal}$. Therefore, ample efforts are made to record elevation of the stations of the desired accuracy for a particular survey. In general, gravity measurements are made over a plain area a few meters away from depression, ponds, mound, etc., which can also affect the gravity readings.

Preprocessing of Field Data

Gravimeters are highly sensitive and they are affected by the changes caused due to the mechanical and environmental changes such as jerks, pressure, and temperature. Gravimeters measure variations in the gravity field, thus the measurements using them are required to tie with the base stations where the absolute values of the gravity field are known. Therefore, measurements need to be corrected for factors influencing measurements to achieve the needed accuracy. There are mainly two corrections, namely (1) drift correction and (2) base loop correction, which are applied during course of the field work.

Drift Correction

When the repeat observations are made by a gravimeter at the same location, it is found to be varying with time. The variation in the gravity field with time is caused due to several geophysical phenomena (Tiwari and Hinderer 2011). In a

gravity survey, time-varying gravity field is primarily attributed to the tidal effect and nontidal changes, caused due to the mechanical behavior of the gravimeter and contributions from atmospheric or hydrological effects during few hours of repeat observations. The peak to peak tidal effect is about 300 μGal during new moon day and can be precisely calculated for specific locations using standard available software such as ETERNA (Schüller 2015). However, precise estimate of tidal effects that include both the solid Earth and ocean loading contributions is not straightforward (Van Camp et al. 2016).

The nontidal variation is referred as drift of the gravimeter (Fig. 1). This is normally $\sim 0.0\text{--}0.03$ mGal/h and is corrected after removing tidal effects computed for that specific location. The drift correction is estimated by making repeat observations at the interval of 1–2 h and the difference in the two nontidal gravity values, known as drift of the instrument, is distributed proportionally to the other observations made during that period. Figure 1 shows the variation of the gravity field with time, tidal effect, and drift at Hyderabad. Repeat observations at a fixed location are also important to understand the condition of gravimeters. If drift of the gravimeter is more than a permissible limit of <0.05 mGal/h, the instrument needs to be thoroughly checked for scale adjustments, battery, etc. or survey needs to be redone.

Base Loop Correction

Gravity base stations are the points where the absolute value of the gravity field is known to an accuracy of 0.01 mGal (10 μGal) and are used to obtain the absolute value of the gravity field at the stations in the field by measuring its variations with respect to base stations. There are primary base stations in the country usually at fixed locations such as railway stations, airports, etc. In any gravity survey, a network of secondary bases is established encompassing survey block, which is connected to any of the known primary base. To achieve the accuracy, a particular procedure of measurements is followed. The bases are connected by looping three times between two bases A and B as A-B-A-B-A-B (A and B being two stations, Fig. 2) and occupying them usually within an hour to ensure that the instrument drift is linear and minimum. This measurement procedure is referred to as double tie of bases. This kind of looping provides three observations at every base, which are corrected for the drift of the gravimeter based on consecutive five readings. The consistent value from the three observations or the average of close-by readings if they are not consistent is chosen for every base station. In case of large survey area such as in a regional survey or hydrocarbon exploration, bases are first established in the region that are subsequently used to tie the gravity stations for their absolute values and simultaneously used for drift correction so as to avoid reoccupying same

Gravity Method, Surface, Fig. 1 Observations of gravity changes at Hyderabad for a day. Tidal and drift of the instrument are plotted separately

Gravity Method, Surface, Fig. 2 A and B are two bases that are occupied five times starting from A to B and going back and forth that provide three diurnal corrected readings at each station which are used to obtain correct reading at base stations

base after 2 h. In these cases, the survey starts from a base station and closed at some other base station after every 1–2 h. The difference in the gravity field is adjusted with respect to their absolute values distributed to the station occupied during that period.

The bases are established on permanent structures for easy identification during the survey and afterward. Figure 3 shows a typical example of a network of bases, which shows the differences in the gravity values between two bases along the arms with arrows showing toward higher values. These differences along the arms of a network (loop) are added or subtracted as the case may be depending on the direction of the arrows to obtain the difference at closing base of the loop. Ideally, it should be zero, but in all practical surveys a difference is found, which is known as closed loop error (CE). This difference is divided by number of arms that gives the distribution error (DE). The arrow inside the loop points in the direction of the positive loop error. In this case, station number 1 is a primary base that is used to establish secondary bases in the survey block for ease of recording the gravity readings in the survey block. Initial checks for loop closure errors are done in the field itself in order to repeat the erroneous bases in case the loop error is found to be more than the permissible error. The permissible error for the closed loop is $0.02 \sqrt{n}$ mGal, where n is number of arms in a loop. Sazhina

Gravity Method, Surface,

Fig. 3 Closed loops of gravity base stations for loop correction. Station numbers are marked as filled circle with arrows indicating toward the increasing values. The closing loop error (CE) is the departure of vector algebraic sum of the each arm (differences in the observed gravity field at adjoining bases) from zero. Observed gravity difference between two adjoining stations (values of arm) is written on the corresponding arm and CE is also written for each loop. Distribution error (DE) is CE divided by number of arms in the loop, which is added to each loop to arrive final values

and Grushiny (1971) have provided detailed description of these corrections under “Adjustment of Gravity Networks” similar to geodetic networks. Having established the requisite number of base stations in an area, the gravity observations at various stations are tied to these bases within a maximum time limit of 1–2 h for drift correction during that period. In regional surveys where survey is conducted along roads at station spacing of 3–5 km, it may not be possible to make loops. However, as the desired accuracy of the gravity data in this survey is limited to 1 mGal, bases can be tied along the roads at about 20–30 km interval as A-B-A-B which provides two drift-corrected readings at every base. The average of the two readings is taken as the base value. In case of mineral exploration, if the area is small and isolated far away from any known base, an arbitrary base is chosen near the camp with any arbitrary value, for example, 0, 100, 1,000, etc., and all the readings are reduced to this arbitrary base value. This provides the gravity anomalies in the survey block with reference to the arbitrary base. In case it is desired, this arbitrary base can be tied to standard bases in the nearby region even after the survey and observed gravity values at stations are updated with reference to the absolute value of the gravity field at the base station accounting for the arbitrary value adopted previously for the survey.

There are several other corrections like latitude, terrain, elevation corrections, etc., that are applied to the observed gravity field at a station to obtain Bouguer anomaly or simply gravity anomaly at a station (Lafehr 1991; Gotze and Li 1996). These corrections are dealt under data reduction or preparation of gravity anomaly maps.

Marine Gravity Survey

The fundamental difference of marine gravity survey from the land survey is measurements on moving platform, which distorts the measurement accuracy. However, if the speed and accelerations are measured, the corresponding corrections might be applied to the gravity data. Nevertheless, the measurement accuracy on the moving platform like ship will not be as accurate as measurements made on ground. The standard accuracy of marine gravity survey is an order of magnitude less than ground survey. The sea state poses another difficulty in the marine survey; it is apparently calm in the deep water and more predictable than the shallow sea or near the coast. Thus, marine gravity measurements are generally corrected for effects of moving platform, Earth’s tide, drift, and adjusted for crossover tracks as briefly explained below.

Moving Platform Correction

The gravity field measurements are distorted due to movement of ship, as well as due to horizontal and vertical accelerations, which can be corrected and eliminated by using supplementary data. They are classified into three categories (Dehlinger 1978).

- *EOTVOS corrections*: When a ship moves, particularly in the east west direction, it experiences centripetal accelerations about the Earth’s axis that modifies the acceleration due to gravity. This can be precisely corrected if the speed and heading of ship is known.

- *Corrections for horizontal and vertical accelerations:* These corrections are applied to gravity measurements for any horizontal and vertical motion of the platform. In the modern type of gravimeter, they are adjusted by designing stabilized platform or gimbal-suspended systems. They are also removed using GPS data and then averaging of several gravity values.
- *Corrections for cross coupling accelerations:* This correction is applied to a beam type of gravity measuring instruments when it is rigidly attached to stabilized platform. The error occurs when horizontal and vertical components of ship accelerations have equal periods and have a phase difference.

Earth Tide Correction

As discussed above, Earth and ocean are subject to the gravitational attraction of Sun and Moon. Over the land, major part of tidal effect is perturbation of solid Earth; however, over ocean the perturbation of outer water surface also has pronounced effect. Therefore, tidal correction applied to ship-borne gravity data should have a model of both solid Earth and ocean (Van Camp et al. 2017).

Drift Correction

All the marine gravity surveys start with known absolute gravity value at the port of sailing and closed to the known gravity station at the end of survey. Since the time of reoccupation of known gravity bases (reference stations) are generally weeks to month, the drift computed are not very accurate. Nevertheless, all the spring associated gravity meters also have long time drift that are generally taken into account while closing the marine survey though they are often small.

Network or Crossover Adjustments

The problem of offset in the marine gravity survey is quite known. It arises due to several reasons (Wessel and Watt 1988). One of the main reasons of offset is mechanical tare or jar of the spring type of gravity meters. Cross over corrections in the same leg of the marine survey is similar to close loop correction discussed for land survey. In case of marine survey over a block, a cross cutting profile is recorded that is used for instrumental check, drift, and data accuracy.

Design of Survey

Designing of gravity survey is a vital component to optimize the resources according to the geological problems. Following are the details.

Regional Surveys for Geodynamic Studies

As the name indicates, these surveys are basically regional in nature and are conducted in large regions for geodynamic studies especially for crustal and upper mantle structures. These surveys are carried out along roads and tracks at a station spacing of 3–5 km, which delineates long wavelength anomalies related to large-scale structures and density inhomogeneities. Anomalies recorded in these surveys are of the order of tens of mGal (10–100 mGal) spread over a few hundred km (~100–1,000 km). The accuracy of such surveys is limited to ± 1 –2 mGal that can be obtained by controlling elevation of stations using DGPS with accuracy better than 1 m in elevation.

Hydrocarbon Exploration

There are two aspects of gravity surveys for hydrocarbon exploration on land, namely (a) reconnaissance gravity survey and (b) detailed/integrated gravity surveys (Nettleton 1976).

Reconnaissance Gravity Survey

Gravity surveys for exploration of hydrocarbons are basically conducted as reconnaissance surveys to delineate basement structures and structures in sedimentary basins to delimit the areas for seismic surveys. It is generally carried out in a large area covering a specific basin along roads and tracks at a station spacing of approximately 2.0 km. It is planned in such a way that network of stations at about 2.0 km spacing are available in the entire region. The order of gravity anomalies expected from such structures are of a few mGal in amplitude, and therefore, the desired accuracy of such surveys are ± 0.1 mGal. Station elevation is therefore obtained by geodetic leveling or DGPS providing elevation to an accuracy of a few cm (<10 cm). To check the accuracy of recorded gravity value, 5–10% of gravity stations are repeated on different days and preferably by different observers. In ocean, surveys are conducted along profiles 4–5 km apart over a specific block and bathymetry is recorded with echo sounder.

Detailed/Integrated Gravity Survey

While conducting seismic surveys for exploration of hydrocarbons, it is a general practice to follow the same profiles by gravity surveys at closer stations spacing of 0.5–1 km. These surveys are basically conducted for an integrated approach to supplement the information derived from seismic surveys and delineate structures within the sediment. The desired accuracy of such surveys are ± 0.01 mGal (10 μ Gal), and therefore, station location and their elevation to accuracy of a few centimeter (<5 cm) are usually obtained from geodetic surveys or dual frequency DGPS. In case of shallow gas occurrences, such surveys can be conducted over a grid with both profile and station spacing of 10–100 m as the case may be. At

the places where reflection seismic data is poor, gravity survey is conducted to supplement the seismic.

Surveys for Minerals, Groundwater, and Engineering Sites

The application of gravity survey for mineral and groundwater exploration primarily lies in delineating surface/shallow structures such as faults, fractures, etc., which may be mineralized (Parasnis 1997). Same is the case with engineering sites where shallow structures such as faults, fractures, etc., are delineated to avoid those sections for large scale constructions such as dams, power plants, etc. The survey procedures for application to these studies are therefore, similar in logistics. They fall under two categories, namely, reconnaissance and detailed/integrated surveys.

Reconnaissance Survey

This kind of survey is carried out to limit the area of interest from a larger area. It is conducted along profiles separated by a few hundred meters a part (100–500 m) at stations spacing of a few tens of meters (10–100 m). If the area is large and inaccessible to lay down specific profiles, it is conducted along available roads and motorable tracks at a station spacing of a few tens of meters (10–100 m). Due to desired accuracy of gravity data, elevation of stations in these surveys are obtained by geodetic leveling or DGPS, providing elevation to an accuracy of a few centimeters (<10 cm). If the area is not large and accessible, a base line is laid out parallel to the general strike of the geological formation in the center of the block and profiles are laid out perpendicular to it at desired intervals. Stations are marked along the profiles at regular intervals by geodetic survey or using DGPS. Based on these reconnaissance surveys, promising zones and geologically significant structures such as faults are delineated which are followed up by detailed gravity and other geophysical surveys such as electrical, electromagnetic, etc. In case of surveys for engineering sites, same reconnaissance procedure is followed to delimit the area as described above for mineral exploration.

Detailed/Integrated Gravity Survey

Detailed gravity survey for the mineral exploration is basically limited in areas of a few square meters and are carried out in grids with profiles and station spacing of a few meters (1–10 m) or may be even less depending on the size of the area and the target. A baseline is laid out parallel to the general strike of the geological formations, and profiles are laid perpendicular to it at almost same spacing of 1–10 m as per requirement of particular survey. Stations along the profiles are marked by the geodetic survey at the same interval as profiles forming a grid. In certain cases, the observed gravity anomaly may be less than 0.1 mGal, which require survey accuracy of about 0.01 mGal (10 μ Gal).

Summary

Gravity method, surface includes both onshore and offshore measurements of the gravity field of the Earth for geodynamic studies and resource exploration. Accuracy of the gravity survey required for various purposes and precautions to be observed in this regard are discussed. Geodynamic studies to an accuracy of 1–2 mGal can be carried out using normal gravity survey but resource exploration usually requires high-resolution gravity survey to an accuracy of $\sim 10 \mu$ Gal using microGal gravimeters. In such cases, base loop correction in ground surveys and correction for crossover points in marine surveys are essential and are emphasized.

Definition

Gravity modeling Explaining the variations of the external gravity field of a body in terms of its internal density variations. Applications range from oil prospecting to the deep structure of the Earth.

Inverse problem In Gravity modeling, the forward problem is to compute the external gravity field of a body knowing its internal density distribution. The inverse problem is the opposite, and is much more difficult to solve for.

The Gravity Modeling from a Theoretical Point of View

Gravity is an elusive quantity to deal with, but a powerful one. This is mainly because unlike electromagnetic forces, gravity cannot be shielded as there are no negative masses. We refer to LaFehr (1980) and Milsom (1996) for an introduction to the gravimetric techniques (see also ► “Gravity Method, Principles”), and Zidarov (1990) for the subtleties of gravimetric inversion. Good monographs are available on the theory and computational aspects of gravity modeling. The one from Blakely (1996) is particularly exhaustive (see also ► “Gravity Anomalies, Interpretation”). Here we give just a short introduction, with emphasis on the modeling directly done on the data, and not on its spectral transforms.

A landmark success of the application of gravimetric interpretation is the identification of the Chicxulub crater buried underneath the Yucatan Peninsula (Hildebrand et al. 1991, Fig. 1, see ► “Impact Craters on Earth”).

The reasons why gravity is so elusive are profound and lie deep in potential theory. Let us start with a simple example. The radial gravity outside a homogeneous sphere of mass M and radius r is given by GM/R^2 , where G is the Newtonian constant and R the distance from the center of the sphere. But

Gravity Modeling, Theory and Computation, Fig. 1 The Chicxulub structure (diameter 180 km) is widely believed to be the remnant of the impact that killed the dinosaurs 65 millions of years ago. This structure was identified on a gravity map of the coast, with no other visible evidence. The impacting asteroid that formed the crater was at least 10 km in diameter. (Image source: Shuttle radar topography mission, Chicxulub Crater Gravity Map with Cenotes Shown as White Dots with the Yucatan Coastline Being the White Line)

r does not intervene in the computation, as long as $R > r$. This means that two homogeneous spheres of radius r and r' have the same external field, as long as they have the same mass. This non-uniqueness has been studied in detail and theory shows that a 3D repartition of density that causes a gravity anomaly can be split in two additive parts: one that is harmonic, that is, that satisfies the Laplace equation, and another that is non-harmonic. Only the harmonic part of the anomalous density can be unambiguously reconstructed from the anomalous gravity signal (Moritz 1989; Vanicek and Kleusberg 1985; Ballani et al. 1993). The non-harmonic part of the density belongs to the so-called null-space of the model. In terms of geophysics, a typical example of non-uniqueness is shown in Fig. 2.

Far more useful is to note that the ambiguity in gravity modeling can be reduced, or even reduced to zero if we know the support, or mathematically, the spatial extension of the density anomaly. For example, if we know by other means the

Gravity Modeling, Theory and Computation, Fig. 2 Each of these underground bodies (gray) creates the same gravity anomaly. If one supposes that the body is reduced to a point mass, one can infer from this assumption the maximum possible depth for the causative body. (Image source: Dubois and Diamant 2005, redrawn)

radius r of the homogeneous sphere, the density ρ is automatically fixed, with $g = GM/R^2$ by $M = 4/3 \times \pi \times \rho \times r^3$.

Chao (2005) has extended this reasoning to the modeling of gravity in terms of spherical harmonics (see ► [“Spherical Harmonic Analysis Applied to Potential Fields”](#)). If we consider a 2D spherical skin covering the Earth, the inverse solution of the surface density distribution is unique. The latter applies quite readily to the inversion of time-variable gravity signals originating from within the crust (such as those observed by the GRACE/GOCE space missions, see ► [“Gravity Method, Satellite”](#)).

Another possibility is to suppose that the density known a priori. In that case, the radius of the sphere instantly follows. This seems trivial, but it is not. It has been demonstrated that the gravity field outside a body can be totally explained by a combination of point masses, linear masses, and sheet masses that lie deep inside the body (Zhdanov 1988). But here also, this result is of little help for the geophysicist. Moreover, the inverse gravity problem is unstable: small variations in the data (errors) can cause unbounded variations in the solution. Technically, the inverse gravity problem is ill-posed in Hadamard’s sense (1902, see also Sabatier 2000 and Menke 1989, and ► [“Inverse Theory, Global Optimization”](#)).

The core fact that permits a useful application of gravity anomalies in geophysics is that these anomalies, even contaminated by noise, reflect *real* structures, that is, structures that *we know* have a reasonable density contrast with the surroundings, and/or exhibit a density that varies smoothly inside the expected structure – except at the edges or along faults – and/or are located inside a given volume. For example, we know from borehole measurements that an iron ore is located between two depths: one at $-1,000$ m and the other one at $-2,000$ m. To have bounds on the possible densities

and/or the locations reduce tremendously the world of possibilities. In short, we are then looking for *plausible* structures.

With such cautions and restrictions, gravity modeling is a powerful tool if correctly used. The best use of gravity measurements is to team them up with other measurements with different null-spaces, like magnetic surveys or even seismic imaging. For example, the velocity of seismic waves increases with density, and the anomalous delays of propagation are linked to the anomalous velocity field (and so to the density through an equation of state) by an averaging integral along the ray known as the Radon transform (Trojan and Hayakawa 2002). A joint seismic/gravity inversion is a powerful tool and probably the best way to remove non-uniqueness (Strykowski 1998, see also ► [“Seismic Tomography”](#)).

But this is hardly done in practice. The driver for field measurements is cost. A gravity survey, even on remote areas, is cheap, and often done as a precursor to more expensive and accurate methods, like seismic tomography. Gravity modeling thus allows to identify promising structures on its own. The game is tricky, as the observed gravity is of course affected by noise, but also by data processing (see ► [“Gravity, Data to Anomalies”](#)). Data processing consists for example of correcting the gravity data for drifts, referring to some “constant” reference in altitude (usually the geoid), and removing the gravity signal of the topography (Bouguer correction, see ► [“Gravimeters”](#)). Besides, the gravity signal is by nature nonlocal, and sums up the signature of other distant bodies or interfaces, like the Mohorovic discontinuity. These distant signatures must be guessed and withdrawn from the gravity signal *before* any local geological interpretation is undertaken (see ► [“Gravity Data, Regional: Residual Separation”](#)).

There are two ways to do this. One is to use direct modeling with feedback. Technically, an operator draws a 2D *educated* guess of the plausible structure (see Fig. 3) on a tablet or other graphic device, and the computer program derives the anomalous gravity model caused by the structure and draws it against the real signal. The operator then modifies slightly the guessed structure in order to obtain a better match with the real signal. For the geophysicist, “anomalous gravity” is synonymous of “Bouguer anomaly,” that is to say a measurement of gravity corrected for the variation of altitude and for the topography-induced variations. Other definitions of “anomalous gravity” are possible. For example, it is theoretically possible to work indifferently with geoid undulations or Bouguer anomalies. In practice, the modeling of geoid undulations is reserved for very-large-scale structures in isostatic equilibrium (see ► [“Isostasy”](#)), while Bouguer anomalies usually refer to small- and medium-scale structures (see ► [“Gravity, Data to Anomalies”](#) and ► [“Geoid Undulation, Interpretation”](#)).

This process can be automated with the computing code adjusting step by step the shape of the structure to exactly

Gravity Modeling, Theory and Computation, Fig. 3

The geological body is approximated by a polygonal structure of infinite length perpendicular to the paper sheet and of constant density contrast with the surroundings. The game is to move the summits of the polygon in order to match (solid curve) the observed gravity (needles)

match the observed gravity anomaly. With some more complexity in terms of calculus, 3D modeling can be done in almost the same manner, with polyhedra replacing polygons. But there is a huge difference at another level. A human operator has always trouble to visualize and modify 3D solid models, even with the assistance of powerful 3D graphic representations. Such a tedious tool is used with parsimony. Efficient formula that replaces volume integrals by integrals along vertices have been developed by several investigators, from Talwani et al. (1959), to Tsoulis and Petrovi (2001) to implement polygon/polyhedron calculus.

For 3D modeling, a better approach is to discretize the volume where we are seeking for the geological structure in tiny adjacent cells of simple fixed shape (e.g., cubes) but of unknown densities. It is important to note the difference with the previous approach: by looking at the densities, we obtain a mathematically linear problem, in the sense that the effect of each cell sums up additively in the gravity model. To the contrary, altering the skeleton of a polyhedron of constant density (even only a single corner point) has a non-additive effect on the computed gravity. Technically, we are dealing with a non-linear model. Non-linear problems are intrinsically much more difficult to solve for.

The Linear Inverse Gravimetric Problem

Let us focus on the linear gravimetric inverse problem, illustrated in Fig. 4. We have to define how the discrepancies between measurements and computed gravity from the model are accounted for. The usual way is to measure this discrepancy as a Euclidean distance, by summing up the square of the differences per data point between measurements and computed gravity, and then taking the square root of the sum. This is called the L2 norm of discrepancies. Another way is to sum up the absolute values of the discrepancies. This is called the L1 norm of discrepancies. Specialized computer languages (not specialized libraries) able to

Gravity Modeling, Theory and Computation, Fig. 4 The linear inverse gravimetric problem. The subsurface is divided in small squares (2D, or pixels) or small cubes (3D, or voxels), and we are looking for the anomalous densities for each square or cube. (Image source: Blakely 1996, redrawn)

directly tackle L2 norm problems and Bayesian inferences have recently being commercialized (Davidson-Pilon 2016). Approaches where the number of parameters in the inversion process is not kept fixed (Transdimensional Bayesian Algorithms with Monte-Carlo framework) are also gaining momentum (Izquierdo et al. 2020). See also in this Encyclopedia ► “Inverse Theory, Monte Carlo Method.”

The set of all unknown densities x over the mesh and the set g of the gravity measurements on the ground are linked through the matrix relation $Ax = g$. In the frame of the L2 norm, solving for the ill-posed inverse linear gravimetric problem, consists of finding a set x of densities that verifies at the best this relation, and fulfilling at the same time another relation of the form $Bx = k$, where k is another physical or mathematical quantity. For example k can be magnetic measurements and B a design matrix linking densities to magnetic measurements. If we add in such way “sufficient” physical information, the solution of this augmented problem becomes

unique. Very often, additional physical information is lacking, and uniqueness is imposed by setting $B = I$ and $k = 0$, where I is the identity matrix. This is equivalent to looking for a set x of densities that realizes a compromise between $Ax = g$ and $x = 0$, that is, an x that explains the gravity signal and is not too large (i.e., close to zero). This is known in the literature as a Tikonov–Arsenine (1976) regularized inverse or Marquardt–Levenberg inverse (Levenberg 1944; Marquardt 1963). Technically, the solution depends also on the way that the hidden Euclidean spaces used to set up the problem are defined. They are not necessarily orthonormal spaces. The angular separation of their axes and unit lengths can carry additional information about the physical problem (called in the literature as “a priori weights”). Tarantola (2005) gave a complete survey of the probabilistic setting for the Tikonov–Arsenine formula, with the weights seen as the inverses of a priori covariance matrices. The covariance linked to I is especially important as it controls to which extent the density contrasts found are “reasonable.” A density contrast of 0.2 is sound; a density contrast of 20 is not, even if the computed gravity matches more closely the observed signal!

The simplest form of the Tikonov–Arsenine inverse formula is of the form:

$$x^*(p) = \text{inv}(\text{trans}(A)A + pI)\text{trans}(A)g \quad (1)$$

where $x^*(p)$ is the solution of the inverse problem (here densities over the mesh), A is the design matrix defined above, p is a scalar parameter, I the identity matrix, and g the set of gravity measurements. In the Tarantola–Valette approach, p is the ratio between the variance of the noise error and the “variance” (the size) of the expected solution with respect to zero. The scalar p is the “smoothing” parameter. The geophysicist chooses “by hand” p in order to have both “reasonable” L2 residuals, defined as $\text{trans}(Ax^* - g)(Ax^* - g)$, and a reasonable L2 size (densities) of x , defined as $\text{trans}(x^*)x^*$.

This solution x^* minimizes, with a unique minimum, the following functional (or cost function) $Q(x)$ with respect to x :

$$Q(x) = \text{trans}(Ax - g)(Ax - g) + p \text{trans}(x)x \quad (2)$$

Without doubt, the celebrated Tikonov–Arsenine formula is the workhorse of gravity inversion.

Another approach, also very popular, but un-implementable for large problems, is to look at the so-called singular value decomposition of A , a generalization of the eigenvalue decomposition of square matrices (Campbell and Meyer 1979, see ► “Inverse Theory, Singular Value Decomposition”). The use of parallel computing and especially GPU (Graphical Processing Units) is a recent way to alleviate the computational burden (Akimova et al. 2018).

Looking at a solution of the inverse problem in terms of the L1 norm seems just a little adjustment with respect to the L2 norm. However, it is a totally different approach. Let us imagine that we have a set of n gravity measurements and a mesh of m cells, assuming that n is larger than m . Technically, the problem is overdetermined, with a matrix A that has many more lines than columns. To solve for this system in the L1 sense consists of solving with respect to x each subset of m lines of A (each subsystem is now square with a trivial inverse), and looking at the solution that gives the best L1 residuals with respect to the complete matrix A . There are $n!/m!(n-m)!$ subsystems. For 1,000 measurements and 50 cells, a computer crushing numbers from the dawn of the universe will have trouble to handle this inversion. Thankfully, Dantzig and colleagues (see Branham 1990) found a way to carry out the L1 inversion with on-the-shelf computers, called the simplex algorithm (linear programming, see ► “Inverse Theory, Linear”). This type of inversion of gravity data has also to be supplemented with a priori (external) constraints to obtain a geologically “sound” solution, for example, by imposing that the inertia moments of the repartition of densities are minima (Cuer and Bayer 1980), or by looking at extrema solutions, for example, the “ideal” body of Parker (1975, see also Goodacre 2006), that is, the set of densities characterizing the geological structure that gives a minimum density contrast with the surroundings.

This type of inverse modeling has been revived recently by the use of neural networks. Neural networks are nothing new, as they were introduced in 1958 (see Widrow and Lehr 1990, for a review of the early developments). The main idea, for the linear case, is first to have a fixed discretization of the subsurface, like the subsurface mesh shown in Fig. 4. Secondly, families (indexed by an integer i) of pixels or voxels densities are generated over this mesh, following a given strategy (for example approximating an ore deposit). Each family can be arranged as a vector “signal” X_i and generates a corresponding Y_i gravity signal (as the profile A in Fig. 4). It then can be demonstrated that the best forward linear link $Y = M X$ between the two families, ordered as matrices in consecutive columns $X = \{X_i, \text{ for all } i\}$ and $Y = \{Y_i, \text{ for all } i\}$ is given by $M = Y X^+$ where the $+$ denotes the pseudo-inverse (or Moore–Penrose inverse) of a matrix (Campbell and Meyer 1979). The best inverse linear link $X = N Y$ is symmetrically given by $N = X Y^+$ (see an application in Barriot et al. 1999, Annex B). This a supervised learning procedure in the modern jargon of artificial intelligence, and the inverse operator N can be used to obtain a best guess of an unknown x from a given measured y by $x = N y$. We can say that N represents an a priori knowledge about the expected subsurface repartition of densities, as it is built from a family of acceptable, from a geophysicist point of view, repartitions of subsurface densities. We refer to Shimelevich et al. (2019) for a recent application in gravimetry and geoelectrics modeling, and to

Valentine and Sambridge (2020a, b) for an overview of inverse gravimetric problems in the light of machine learning.

The Nonlinear Inverse Gravimetric Problem

In this section we come back to the polygon/polyhedron modeling of gravity anomalies, where we assume that the density of the body is uniform.

Mathematically, the problem expressed as $g = f(x)$, where now x is the set of coordinates of the corner points, and is nonlinear. We want to find a set of coordinates that explain “at the best” the gravity signal, that is, $g(\text{observed}) - f(x)$ is kept to a minimum, for example, with respect to the L2 norm.

We then have to minimize a cost function of the form:

$$Q(x) = \text{trans}(g - f(x))(g - f(x)) \quad (3)$$

There is an important difference with the linear case. We can have several well-separated, inherent minima to this functional (Fig. 5). There are two ways to solve for this inverse problem. The first one is to linearize the problem, that is, to look at a solution close to a known estimate x_0 , that is, by writing that $x = x_0 + dx$, with a dx bounded in some way.

A typical illustration in gravimetry is to look at the shape of an unknown interface between two strata of different and constant densities (see Fig. 6). This is an extension of the polygonal model where some points are pushed to infinity and has been discussed by Tarantola and Valette (1982) in their milestone paper, an extension of the pioneering work of Cordell and Henderson (1968). This is often used to refine a model obtained by the modeler from a priori geological evidence, but can be hardly used without any a priori knowledge of the solution. The Backus and Gilbert approach (1968), very popular during the 1970s, can also be seen as a nonlinear problem.

The other approach, more radical, consists in trying to explore the whole set of possible minima of the nonlinear cost-functional. A popular approach to do so is to mimic the biological process of evolution. The genetic algorithm of Holland (1975) can be summarized in four basic steps: coding, selection, crossover, and mutation.

Common to any genetic algorithm is the digitization of an a priori and sufficiently populated list of model parameters using a binary code scheme (for example, we know that the density we are looking for is bounded by 2.5 and 2.8). Assume that the desired resolution (discretization) is 0.01. Then we can make a one-to-one correspondence between a binary word of 5 bits (a “chromosome”) and this discretization. A subset of models is then selected from the model population by using some global fitness criterion, for example, the ratio of each model fitness (evaluated in the L2 sense with respect to the observed gravity and using the one-to-one correspondence) to the sum of all fitness criteria for all models. We then take the models the ratio of which is over a given threshold. For example, for a population of L models, we choose a subset of $L/2$ of “best fit” models. We then mate the $L/2$ models by pairs, each pair bearing two off-springs by recombination of their chromosomes by processes called crossover and mutation that mimic the meiosis of real chromosomes, giving birth to a complete new generation of L models that replaces the old one. Generally, the average fitness increases between generations, since only the best models from each generation are selected for breeding. Other algorithms exist to locate the “best” minimum, like

Gravity Modeling, Theory and Computation, Fig. 6 Modeling an interface between two homogeneous separate strata. The problem is a special case of the polygon/polyhedron inverse problem. (Image source: Tarantola and Valette 1982, redrawn)

Gravity Modeling, Theory and Computation, Fig. 5

(a) The cost function of the linear inverse problem presents only one minimum. (b) The cost function of the nonlinear inverse problem may present several minima, indicating a non-unique solution. (Image source: Dimri 1992, redrawn)

the tunneling algorithm (Levy and Montalvo 1985) or the particle swarm optimization (Monteiro Santos 2010). Neural networks can also be applied to the non-linear case, but it is too early to say whether this is a fashion effect in gravimetric modeling or will lead to real practical tools. We refer to LeCun et al. (2015) for an in-depth review of the latest advances in neural networks and deep learning. Powerful no-cost computer libraries like TensorFlow for deep learning applications are now in wide use (Abadi et al. 2015). Another kinds of supervised learning algorithms are the so-called Support Vector Machines (SVM) classifiers. An application of SVM to gravimetric modeling can be found in Wu et al. (2007). Unsupervised learning as also being attempted (Levassor et al. 2009). See also in this Encyclopedia ► “Inverse Theory, Artificial Neural Networks” and ► “Inverse Theory, Monte Carlo Method”.

Spectral Approaches

Spectral approaches rely on the expression of the gravity signal along a basis of given functions: very often a Fourier decomposition in the planar case or spherical harmonics on a global basis. New basis are gaining a wide acceptance, like wavelets, that are like “sine” or “cosine” waves but with a limited spatial support (Chui 1992). Large classes of inverse gravimetric problems can then be recast as deconvolution problems (Dimri 1992), with all the artillery available from Fourier analysis (Dean 1958; Blakely 1996). Nevertheless, this approach suffers from all the drawbacks of the Fourier analysis, especially the need to smooth the discontinuities of the gravity signal at the edges of the zone of interest (this is of course not the case for spherical harmonics). Such approaches have been used in planetary geophysics to estimate the global and local average depth of the Moho interface on Mars (Zuber et al. 2000) using spherical harmonics modeling of the gravity field and of the topography of the planet, without any other surface or subsurface information. Let us also mention the use of wavelets that permits a multiscale regularized deconvolution of the density variations in the Earth’s crust (Volker 2005).

Summary

Gravity modeling is a cheap tool in geophysical prospecting. It can also be a very potent tool if used with some precaution. This always implies the introduction, both in forward and inverse modeling, of some a priori knowledge of the shape of structures that are guessed, or some bounds about their dimensions or about acceptable density contrasts.

Gravity, Data to Anomalies

Ron Hackney

Petroleum and Marine Division, Geoscience Australia,
Canberra, ACT, Australia

Definition

Gravity anomaly. The difference between gravity measured at a point and a model value at that point that is based on the normal gravity of a reference ellipsoid, corrected for the gravity effects of elevation above the reference ellipsoid and the mass of rock between the point and the reference ellipsoid.

Introduction

The study of anomalous gravity has its roots in geodesy where it is used to determine the shape of the Earth (see ► “Geodesy, Physical” and ► “Geodesy, Figure of the Earth”). Gravity anomalies have also proved extremely useful in the interpretation of subsurface geological structure at various scales. Like many geophysical techniques, resource exploration has been the greatest driver of the use of gravity data (e.g., Nabighian et al. 2005). Gravity anomalies are often useful in the early stages of an exploration program as they provide insight into the form of low-density sediment accumulations (basins) or the location of high-density ore deposits. At larger scales, gravity anomalies provide insight into crustal structure and, most recently, time variations in the long-wavelength gravity field measured using satellites (see ► “Gravity Method, Satellite”) provide insight into changes in polar ice mass and ground-water fluctuations.

Before gravity data are useful in resource exploration or crustal studies, non-geological contributions to the gravity field that obscure the anomalies of interest need to be accounted for and effectively removed. This chapter explains the process of converting gravity measurements to gravity anomalies for geophysical applications. It is important to stress the geophysical context as there are often subtle differences in the way geodesists and geophysicists think of and use the various gravity-related quantities (cf. Li and Götze 2001; Hackney and Featherstone 2003; Hofmann-Wellenhof and Moritz 2006).

Key Parameters

Figure 1 shows the key parameters required for computing anomalous gravity. The relevant gravity quantities for geophysical applications are:

- Gravity measured at the point P , g_P
- Normal gravity on the surface of the reference ellipsoid, γ
- A model or predicted gravity value at the measurement point P , γ_P , derived from γ

The elevation of the point P is also required to account for the decrease in gravity with increasing elevation and the gravity effect of the mass of rock between the measurement point and the reference ellipsoid. Two height quantities need to be considered (Fig. 1). The height of the point P above the geoid, H , is measured along a plumb line, a curved line that is perpendicular to equipotential surfaces (the geoid is the equipotential surface that most closely approximates mean sea

Gravity, Data to Anomalies, Fig. 1 Diagram illustrating the key parameters required for computing geophysical gravity anomalies

level – see ► “Geoid Determination, Theory and Principles”). The ellipsoidal height, h , is measured along an ellipsoidal normal, the line through P that is perpendicular to the surface of the reference ellipsoid. When computed algebraically (i.e., disregarding the vector nature of gravity), the difference between h and H gives the geoid–ellipsoid separation, N , where

$$N = h - H. \quad (1)$$

Observed Gravity

The measured value of gravity at a point P is the value typically determined from relative gravity measurements that are converted to an observed value by tying to an international network of reference gravity stations, currently the International Gravity Standardization Network of 1971 (IGSN71; Morelli et al. 1974). Country-specific datums may also be used (e.g., Tracey et al. 2007), but these are also generally tied to IGSN71. The relative measurements may be made on land or at sea (see ► “Gravity Method, Surface”) or even in the air (see ► “Gravity Method, Airborne”). The relative measurements will have been corrected for instrument drift and Earth tide variations (see ► “Gravity Method, Surface”).

Anomalous Gravity in Geophysics

An anomaly is the difference between something that we measure at a particular place and what we expect from a reference model at that place. In seismology, measured travel times are compared to those expected from simplified models of the whole Earth (see ► “Seismic Tomography”). The resulting travel-time anomalies tell us about regions through which seismic waves travel faster or slower than through the simplified representation of reality. This in turn tells us something about the temperature or composition of the Earth’s interior. In geophysical applications, gravity anomalies are best thought of in a similar way: Measurements of the gravity field at the Earth’s surface are compared to the gravity expected from a reference model of the Earth. The differences in gravity between our measurements and the reference model tell us something about lateral mass-density variations within the Earth.

In this context, a geophysicist generally seeks to remove large-scale, non-geological gravity effects that mask the gravity anomalies that can be related to subsurface density variations (e.g., related to ore deposits, sedimentary basins, or crustal structure). The large-scale effects include Earth mass and rotation and, depending on the application, maybe some or all of the crust and mantle. Most of the large-scale effect is accounted for by normal gravity, the acceleration due to gravity on the surface of a reference ellipsoid, an ellipsoid of rotation that best fits the shape of the Earth (represented by the geoid – see ► “Geodesy, Figure of the Earth”).

If a model value is required at a point that does not lie on the surface of the reference ellipsoid, adjustments must be made to normal gravity to account for gravity effects related to (a) the difference in height between the measurement point and the surface of the reference ellipsoid (because gravity decreases with distance from the Earth proportionally to $1/r^2$) and (b) the body of rock (or water) lying between the measurement point and the reference ellipsoid. Other regional-scale gravity effects that arise from crustal structure might also be removed by a process of regional–residual field separation (see ► “Gravity Data, Regional: Residual Separation”) or filtering (see ► “Gravity Data, Advanced Processing”).

In the geophysical context, anomalous gravity is calculated by subtracting a predicted or model gravity value for a point P from the measured (observed) gravity at that point. This anomalous gravity quantity is technically referred to as a gravity disturbance (cf. Hackney and Featherstone 2003), but the use of gravity “anomaly” is and will likely remain entrenched in the geophysical vernacular. In a geophysical sense, a gravity anomaly can be expressed as

Gravity anomaly = (Measured value) – (Model value), or mathematically as:

$$\Delta g_P = g_P - \gamma_P \quad (2)$$

where

- Δg_P is the anomalous gravity
- g_P is measured gravity at the point P
- γ_P is a predicted or model value of gravity at the measurement point P (our best estimate of the Earth’s gravity field at P that considers Earth’s mass and rotation and the elevation, h , of the point P with respect to the reference ellipsoid)

As illustrated in Fig. 2, the predicted gravity value, γ_P is computed by applying corrections to normal gravity that account for the height of the measurement point above the reference ellipsoid (Free air correction) and the mass of rock that lies between the measurement point and the reference ellipsoid (Bouguer and terrain corrections). Mathematically, the computation of γ_P can be expressed as:

$$\gamma_P = \gamma - \delta g_F + \delta g_B - \delta g_T \quad (3)$$

where

- γ is normal gravity on the reference ellipsoid
- δg_F is the Free air correction
- δg_B the Bouguer correction
- δg_T the terrain correction

The application of these corrections is described in the following section.

Computing Model Gravity at the Measurement Point

A Note on Units

The standard SI unit of acceleration due to gravity is $\text{m}\cdot\text{s}^{-2}$. However, because gravity anomalies are generally about three to seven orders of magnitude smaller than total gravity acceleration, the use of derivative units is more practical. Historically, the mGal was the standard derivative unit ($1 \text{ mGal} = 10^{-5} \text{ m}\cdot\text{s}^{-2}$). The mGal is still in common use, but gravity anomalies and related quantities are often also given in $\mu\text{m}\cdot\text{s}^{-2}$ ($10^{-6} \text{ m}\cdot\text{s}^{-2}$). In this description of the anomaly computation procedure, physical constants are given in standard SI units. This means that unless otherwise stated, the equations presented give quantities in $\text{m}\cdot\text{s}^{-2}$.

Normal Gravity (Fig. 2b)

Normal gravity, γ , represents the gravity effect of a reference ellipsoid whose geometry is defined to best represent the

Gravity, Data to Anomalies, Fig. 2 Illustration of the process of computing anomalous gravity in geophysics. (a) Observed gravity g_P reflects mass below the Earth's surface (light gray shading). (b) Normal gravity, γ , considers only mass below the reference ellipsoid (dark gray shading). (c) The free-air correction, δg_F , accounts for the elevation difference between the point P and the surface of the reference ellipsoid,

but not the rock mass in that space. (d) The Bouguer correction, δg_B , adds the gravity effect of rock mass between P and the surface of the reference ellipsoid, but assumes that rock mass has a smooth upper surface. (e) The terrain correction, δg_T , corrects for the smooth-topped Bouguer plate or cap

shape of the Earth. Because an ellipsoid is a mathematically defined body, computing its gravity effect is straightforward. A closed-form expression for computing normal gravity on the surface of a *geocentric* reference ellipsoid is given by the Somigliana–Pizetti formula (e.g., Hofmann-Wellenhof and Moritz 2006; see also ► “International Gravity Formula”):

$$\gamma = \gamma_a \frac{1 + k \sin^2 \phi}{\sqrt{1 - e^2 \sin^2 \phi}}, \quad (4)$$

where γ_a is normal gravity at the equator of the reference ellipsoid, ϕ is the *geocentric* latitude of the measurement point, and k and e^2 are quantities derived from the parameters describing the form of the reference ellipsoid (Table 1).

Equation 4 is exact and has now been adopted in many countries as a standard when computing gravity anomalies for geophysical applications (e.g., Hinze et al. 2005; Tracey et al. 2007). In the past, simpler expressions were used for computing normal gravity (cf. Li and Götze 2001). These approximate formulae were used largely for computational convenience, but given the measurement accuracy achievable today, their continued use is difficult to justify.

Free Air Correction (Fig. 2c)

Equation 4 gives normal gravity on the surface of the reference ellipsoid. However, the measurement point P is almost never located exactly on the surface of the reference ellipsoid. This means that the model value at a measurement point above the reference ellipsoid will be less than γ . The decrease in gravity above the reference ellipsoid is accounted for by the Free air correction. This correction essentially uses the rate of change in gravity above the surface of the Earth to correct for the decrease in gravity with elevation.

Historically, the value of the Free air correction was approximated as $0.3086 \times 10^{-5} \text{ m}\cdot\text{s}^{-2}/\text{m}$ (i.e., 0.3086 mGal/m), the gravity gradient above a spherical Earth. A more rigorous expression for the Free air correction, δg_F , can be derived from the gradient of normal gravity above the surface of the reference ellipsoid. Normal gravity at a height h above the ellipsoid can be computed directly from (Hofmann-Wellenhof and Moritz 2006):

$$\gamma_h = \gamma \left[1 - \frac{2}{a} (1 + f + m - 2f \sin^2 \phi) h + \frac{3}{a^2} h^2 \right], \quad (5)$$

Gravity, Data to Anomalies, Table 1 Parameters defining the GRS80 geocentric reference ellipsoid (Moritz 2000), the reference ellipsoid currently recommended by the International Union of Geodesy and

Geophysics as representing the size, shape, and gravity field of the Earth with an accuracy sufficient for most geodetic, geophysical, astronomical, and hydrographic applications

Parameter	Name	Equation	GRS80 value
a	Semi-major axis (equatorial radius)		6,378,137 m
GM	Geocentric gravitational constant		$3,986,005 \times 10^8 \text{ m}^3 \cdot \text{s}^{-2}$
J_2	Dynamic form factor		$108,263 \times 10^{-8}$
ω	Angular velocity		$7,292,115 \times 10^{-11} \text{ rad} \cdot \text{s}^{-1}$
b	Semi-minor axis (polar radius)		6,356,752.3141 m
γ_a	Equatorial normal gravity		$9.780\,326\,7715 \text{ m} \cdot \text{s}^{-2}$
γ_b	Polar normal gravity		$9.832\,186\,3685 \text{ m} \cdot \text{s}^{-2}$
k	Normal gravity constant	$(b\gamma_b/a\gamma_a) - 1$	0.001 931 851 353
e^2	First numerical eccentricity	$(a^2 - b^2)/a^2$	0.006 694 380 022 90
f	Ellipsoidal flattening	$(a - b)/a$	0.003 352 810 681 18
m	Geodetic parameter	$\omega^2 a^2 b/GM$	0.003 449 786 003 08
R_e	Arithmetic mean earth radius	$(2a + b)/3$	6,371,008.7714 m

Note that the parameters a , GM , J_2 , and ω are exact defining parameters – the other parameters are derived geometric and physical constants

or the magnitude of the Free air correction, δg_F , to be subtracted from γ can be computed using,

$$\delta g_F = \frac{2\gamma_a}{a} \left(1 + f + m + \left(-3f + \frac{5}{2}m \right) \sin^2 \phi \right) h - \frac{3\gamma_a}{a^2} h^2. \quad (6)$$

The parameters f (ellipsoidal flattening) and m (geodetic parameter) are defined in Table 1.

Bouguer Correction (Fig. 2d)

Once normal gravity is corrected for the vertical separation between the reference ellipsoid and the measurement point, a further adjustment needs to be made for the body of rock between that point and the reference ellipsoid. The gravity effect of this rock is not represented in normal gravity and is not accounted for by the Free air correction. This correction, the Bouguer correction, δg_B , was historically computed by representing the body of rock between the measurement point and surface of the reference ellipsoid as a horizontal slab extending to infinity. The infinite-slab Bouguer correction is given by:

$$\delta g_B = 2\pi G \rho t \quad (7)$$

where ρ is the assumed density of the slab, t is the thickness of the slab, and G is the universal gravitational constant ($6.67428 \times 10^{-11} \text{ m}^3 \cdot \text{kg}^{-1} \cdot \text{s}^{-2}$, the 2006 value recommended by the Committee on Data for Science and Technology, International Council of Science). In most cases, the slab thickness is equivalent to the height of the measurement point above the reference ellipsoid, h . The density of the slab generally takes on a standardized value of $2,670 \text{ kg} \cdot \text{m}^{-3}$, a value that closely represents the average density of crustal rocks (Hinze 2003). In some cases, a density that is more representative of local

geology may be used to minimize the correlation between the Bouguer anomaly and topography. However, using standardized values facilitates the comparison of different datasets and avoids incorporating geological interpretation into the anomaly computation procedure (LaFehr 1991a).

More sophisticated representations of the rock mass below the measurement point take into account the curvature of the Earth's surface. A commonly used representation is the spherical cap, the gravity effect of which is given by (LaFehr 1991b):

$$\delta g_B^{\text{cap}} = 2\pi G \rho [\mu t - \lambda(R_E + t)] \quad (8)$$

where R_E is the mean radius of the reference ellipsoid (Table 1), t the thickness of the cap (generally equivalent to the height of the measurement point above the reference ellipsoid, h), and μ and λ are dimensionless coefficients related to R_E and the angle subtended by the spherical cap at the center of the Earth. The spherical cap is generally taken to extend to a distance of 166.735 km from the measurement point, the distance originally selected by Bullard (1936) to minimize the difference between the gravity effect of the spherical cap and the infinite slab for a range of elevations (cf. LaFehr 1991b). Equation 8 is valid for surveys made on land, but Argast et al. (2009) present an extended form of the equation that is valid for gravity measurements made in the air and at sea.

Terrain Correction (Fig. 2e)

Regardless of whether the Bouguer correction is computed from an infinite slab or from a spherical cap, it is computed for a body with a flat or curved top that does not match topography. Topographic variations can have a significant influence on measured gravity, particularly in areas of high relief (e.g., mountain ranges or near the continental slope). For this reason, it is often beneficial to compute a terrain correction that effectively imparts an irregular surface onto the top of the Bouguer plate or cap.

Various methods exist for computing the terrain correction (cf. Nowell 1999; Hackney and Featherstone 2003), but the methods generally involve dividing the region around the measurement point into a series of rectangular prisms or concentric ring segments. A digital elevation model is then used to determine the average elevation for each prism relative to the height of the measurement point. Accuracy can be improved by using prisms with sloping tops. The size of the prisms is generally increased away from the measurement point as the influence of distant prisms is less than for nearer prisms. To further simplify computations, some methods approximate the more distant prisms as a line mass and fast-Fourier transform techniques have also been developed.

Often the different methods for computing terrain corrections are combined. For example, Hinze et al. (2005) describe the procedure adopted for the North American gravity database that uses segmented rings and estimated topography within 100 m of the measurements point, segmented rings and high-resolution digital elevation data from 100 to 895 m, and vertical prisms and digital elevation data from 895 m to 166.7 km (including corrections for Earth curvature beyond 14 km).

Historically, the most commonly used terrain correction procedure was based on computing the gravity effect of a number of concentric rings divided into individual segments (Hammer 1939). The gravity effect of each prism can be computed from:

$$\delta g_{\text{prism}} = 2\pi G \frac{\rho}{n} \left(r_2 - r_1 + \sqrt{r_1^2 + z^2} - \sqrt{r_2^2 + z^2} \right) \quad (9)$$

where n is the number of prism segments in each concentric ring (zone), r_2 is the outer radius of the concentric ring, r_1 the inner radius, and z is the elevation difference between the measurement point and the mean elevation of the ring segment. The other parameters are the same as in Eqs. 6 and 7. The density, ρ , used in Eq. 9 should be the same as that used for the Bouguer correction.

The Hammer (1939) formulation includes concentric rings out to a distance of 22 km, but ideally terrain corrections should be computed out to 166.735 km ($\sim 1.5^\circ$), the full radius of the standard spherical cap. When terrain corrections are computed to this distance, Earth curvature must also be considered. However, the influence of terrain corrections beyond about 10–20 km from the station is often insignificant and sometimes ignored.

Anomaly Computation

Once the Free air, Bouguer, and terrain corrections are applied to normal gravity, the gravity anomaly at the point P can be computed from Eqs. 2 and 3, i.e.,

$$\begin{aligned} \Delta g &= g_P - \gamma_P \\ &= g_P - (\gamma - \delta g_F + \delta g_B - \delta g_T) \\ &= g_P - (\gamma_h + \delta g_B - \delta g_T) \end{aligned} \quad (10)$$

In Eq. 10, the term in brackets represents the predicted or model value of gravity at the measurement point. The Free air correction is subtracted because normal gravity is reduced above the surface of the ellipsoid (Fig. 2c), while the Bouguer correction is added because the extra gravity effect related to the body of rock between P and the reference ellipsoid is not included in γ (Fig. 2d). The terrain correction must be subtracted from γ (Fig. 2e) to remove the effect of the non-existent slab/cap mass assumed to fill valleys and to reduce the model valley of gravity for topography higher than the measurement point (mass above the measurement point reduces gravity).

Once the model value of gravity is subtracted from the measured value of gravity at P , the remaining quantity is the anomalous component of the gravity field that cannot be explained by large-scale gravity effects related to the Earth's shape and rotation, changes in gravity with elevation, and the bulk influence of rock below the measurement point. The resulting anomalous gravity reflects subsurface density variations and can be interpreted geologically (see ► “Gravity Anomalies, Interpretation” and ► “Gravity Modeling, Theory and Computation”).

Other Factors

Atmospheric Correction

The parameters that define the GRS80 reference ellipsoid (Table 1) rely on satellite-based measurements, meaning that normal gravity includes the mass of the atmosphere. The application of a correction to normal gravity for the atmospheric mass is usually insignificant in comparison to errors associated with terrain corrections, meaning that its application is not essential for many geophysical applications (e.g., Featherstone and Dentith 1997). Nevertheless, the application of an atmospheric correction is included in new standards for gravity anomaly computation (e.g., Hinze et al. 2005; Tracey et al. 2007). If it is to be applied, the value to be subtracted from normal gravity can be computed using (Wenzel 1985).

$$\delta g_A = 0.874 - 9.9 \times 10^{-5}h + 3.56 \times 10^{-9}h^2. \quad (11)$$

This equation has an accuracy of about $0.01 \times 10^5 \text{ m}\cdot\text{s}^{-2}$ to 10 km elevation.

Further Isolating Anomalies of Interest

The Bouguer anomaly computed using Eq. 10 is dominated by the gravity effect of crustal-thickness variations that

more-or-less isostatically compensate for topography (thick crust under mountains, thin crust under ocean basins – see ► “Isostasy”). While the Bouguer anomaly is useful for constraining crustal-scale studies, the gravity effect of smaller-scale density variations within the upper crust (e.g., ore deposits or sedimentary basins) is often obscured by the long-wavelength gravity signature related to crustal-thickness variations.

The long-wavelength component of the Bouguer anomaly can be removed using regional–residual field separation techniques (see ► “Gravity Data, Regional: Residual Separation”). Alternatively, some form of isostatic compensation can be assumed (see ► “Isostasy”) and the gravity effect of the Moho that compensates for topography can be computed and subsequently subtracted.

Distant Relief

Computation of the Bouguer correction and associated terrain corrections are generally made out to a standard distance of 166.735 km. In certain circumstances, the gravity effect of topography beyond this distance can be significant (e.g., surveys in areas of high topography and continental- and global-scale studies: LaFehr 1991a; Mikuška et al. 2006). Users of gravity data should be aware of these distant relief effects and consider them if necessary.

Efforts to include the effects of whole-Earth topography are emerging. For example, Kuhn et al. (2009) present a grid of terrain corrections for the Australian continent that considers topography globally and Tenzer et al. (2009) computed gravity anomalies for the entire Earth that incorporate corrections for global topography.

The Geophysical “Indirect Effect”

The formulation for anomalous gravity described here (Eq. 2) is the most logical way in which to think of gravity anomalies for geophysical applications. However, the process of anomaly computation is often described as a reduction of g_P to the sea level datum. While this process is useful in geodesy, it is not strictly correct in geophysical applications (Hackney and Featherstone 2003).

The misconception that gravity anomaly computation for geophysical purposes involves reducing gravity measurements to the geoid (or sea level) is partly related to the measurement of elevation. Before the advent of GPS (see ► “GPS, Data Acquisition, and Analysis”), elevations were normally determined by leveling over long traverses from reference tide gauges at the coastline (see ► “Geodesy, Ground Positioning, and Levelling”). Leveling thus provided heights relative to sea level, or the geoid. However, normal gravity is derived from a mathematically defined body, the reference ellipsoid, which does not coincide exactly with the geoid.

The reference ellipsoid is generally chosen to best fit the geoid either regionally or globally, but the ellipsoid never perfectly matches the geoid. This means that if heights relative to sea level are used to compute anomalous gravity, then the corrections applied will either be an under- or over-correction, depending on whether the ellipsoid is above or below the geoid (Fig. 3). The magnitude of this under- or overcorrection is referred to as the *geophysical indirect effect* (e.g., Hackney and Featherstone 2003). Globally, the geoid–ellipsoid separation is about ± 100 m at most, meaning that the geophysical indirect effect varies by about $\pm 30 \times 10^{-5} \text{ m}\cdot\text{s}^{-2}$. This variation can induce long-

Gravity, Data to Anomalies,

Fig. 3 Illustration of the under- or over-correction of model predicted gravity that results when the Free air and Bouguer corrections are computed using heights relative to mean sea level (geoid) rather than relative to the reference ellipsoid. N is defined by Eq. 1

wavelength errors in gravity data, especially in areas of high geoid gradient. For more regional surveys, the effect is generally minor and, in many cases, essentially constant. For regional surveys, the geophysical indirect effect is a bias that will often be accounted for during regional–residual field separation.

With the advent of GPS, elevations tied directly to the WGS84 ellipsoid became readily available. Because the differences in the dimensions of the WGS84 and GRS80 ellipsoids are minor, anomalous gravity can be computed directly from the heights measured by GPS. However, care is required in order to ensure that consistent heights are used for both older and newer datasets. Updated procedures adopted in some countries recognize the need to use heights tied to the reference ellipsoid (e.g., Hinze et al. 2005; Tracey et al. 2007).

Gravity Anomalies for Geodetic Purposes

This entry focuses on the geophysical approach to computation of gravity anomalies, but it is worth outlining the ways in which gravity anomalies are computed for geodetic purposes. In geodesy (see ► “Geodesy, Physical” and ► “Geoid Determination, Computational Methods”), gravity anomalies are used to determine the shape of the Earth using either a “classical” or “modern” approach (e.g., Hofmann-Wellenhof and Moritz 2006). In the classical approach, the geoid is determined using gravity anomalies computed from the difference between surface gravity measurements reduced (downward) to the geoid and normal gravity on the reference ellipsoid. The modern approach leads to the computation of a surface referred to as the telluroid and requires gravity anomalies computed from the difference between surface gravity and normal gravity corrected (upward) to the telluroid. The separation between the telluroid and the surface (the “height anomaly”) can then be used to determine a geoid-proxy referred to as the quasigeoid.

Computation Example: The Central Andes

The Central Andes in South America are an ideal region to illustrate the process of computing anomalous gravity for geophysical purposes. This is because the high topography and associated thick crust lead to large corrections and high-amplitude gravity anomalies. Observed gravity and the different types of corrections, model values, and anomalies for the Central Andes are illustrated in Fig. 4. The gridded data shown in Fig. 4 are based on a dataset that contains more than 4,000 surface gravity measurements (Schmidt and Götze 2006) (Fig. 4a). Figure 4b shows the observed (measured) values of gravity, g_P , that are tied to reference stations linked to the IGSN71 gravity datum. Observed

gravity values are large (9.773 – $9.796 \text{ m}\cdot\text{s}^{-2}$) and the highest parts of the Central Andes are associated with the lowest measured gravity. This is due mostly to the pronounced decrease in gravity with elevation, but the mass deficit associated with the thick, low density crust (with respect to the underlying mantle) also contributes to the decreased gravity in the mountainous areas.

Normal gravity on the GRS80 reference ellipsoid (Eq. 4 and Fig. 4c) shows a north-to-south increasing trend that reflects the pole-ward increase in gravity related to the shape and rotation of the reference ellipsoid. To derive a model value directly at each of the data points shown in Fig. 4a, Free air (Eq. 6) and Bouguer (Eq. 7 or 8) corrections are applied to normal gravity. The magnitude of the Free air correction, δg_F , is shown in Fig. 4d – the correction is largest where topography is highest. The Free air correction is subtracted from normal gravity to account for the decrease in normal gravity with elevation above the reference ellipsoid. The Free air anomaly results when the height-corrected normal gravity is subtracted from observed gravity (Fig. 4g). Compared to observed gravity, the amplitude range of the Free air anomaly is significantly reduced ($\pm 300 \times 10^{-5} \text{ m}\cdot\text{s}^{-2}$).

A map of Free air anomalies (Fig. 4g) is difficult to interpret geologically because it retains a strong correlation with topography. This correlation is modified when the gravity effect of the rock between the surface and the reference ellipsoid is accounted for using the Bouguer correction (Fig. 4e). The Bouguer correction is added to normal gravity (because normal gravity does not include the gravity effect of the rocks) and, together with the addition of the Free air correction, results in a model value, γ_P , that resembles the observed gravity (Fig. 4f). When this model value is subtracted from the observed gravity, the Bouguer anomaly results (Fig. 4h). The Bouguer anomaly of the Central Andes is large and negative (minimum values reach about $-450 \times 10^{-5} \text{ m}\cdot\text{s}^{-2}$), which reflects the thick crustal root beneath the Central Andes.

An isostatic residual gravity map is shown for the Central Andes in Fig. 4i. The regional field (inset between Fig. 4h, i) is computed by assuming regional isostatic compensation of topography using an effective elastic thickness of 20 km (see ► “Isostasy”). Crustal thickness is computed for this model and then the gravity effect of the isostatic Moho is estimated and subtracted from the Bouguer anomaly. The Central Andean isostatic residual field has a vastly reduced amplitude (-150 to $+60 \times 10^{-5} \text{ m}\cdot\text{s}^{-2}$) and bears a closer resemblance to surface geology, particularly the location of active volcanoes. The coincidence between active volcanoes and negative isostatic residual anomalies suggests the presence of low-density material within the crust or that the assumption of regional isostatic compensation is not applicable to the volcanic chain.

Gravity, Data to Anomalies,

Fig. 4 Illustration of the various components of anomalous gravity for the Central Andes in South America. (a) Topography from the GTOPO30 global digital elevation model – points show the location of gravity measurements (Schmidt and Götze 2006) where the various corrections are computed and gridded using a cell size of one arc minute; (b) observed gravity; (c) normal gravity on the surface of the GRS80 reference ellipsoid computed using Eq. 4 – note the latitudinal variation; (d) the magnitude of the Free air correction that is subtracted from normal gravity to account for the reduction in normal gravity above the reference ellipsoid; (e) the Bouguer correction that represents the gravity effect of the mass of rock between the surface and the reference ellipsoid; (f) model value for gravity at the surface that is subtracted from the observed gravity shown in b to produce the Bouguer anomaly; (g) the Free air anomaly; (h) the Bouguer anomaly (map in b minus map in f); (i) isostatic residual anomaly, δg_I , computed by subtracting from the Bouguer anomaly an isostatic regional field (inset between h and i) computed by assuming regional isostatic compensation of Andean topography with an elastic thickness of 20 km. The triangles in (i) show active volcanoes (Trumbull et al. 2006). (Note that the Bouguer anomaly in (h) does not incorporate a terrain correction, but when plotted at this scale, the effect of the terrain correction is not evident)

**Summary**

From a geophysical perspective, a gravity anomaly is best thought of as the difference between measured gravity and a model value, at the same point, that accounts for large-scale, non-geological effects that mask anomalies related to subsurface geology. The model gravity value is derived by correcting normal gravity for the effects of height above the reference ellipsoid (Free air correction) and the

mass of rock between the reference ellipsoid and the measurement point (Bouguer correction). Additional corrections (terrain and atmospheric corrections, indirect effect) improve on the relatively straightforward Free air and Bouguer corrections. Since the earliest use of gravity data, our ability to compute the corrections to normal gravity has improved to the point where simplistic application of the corrections is giving way to procedures that consider global influences.

Depending on the application, long-wavelength field components remaining in the Bouguer anomaly may also be removed (isostatic correction or regional–residual field separation). Gravity anomalies can then be used to constrain geological interpretations of relatively shallow crustal features (e.g., basins, ore bodies, or even archeological sites), or be used to examine crustal structure and isostatic state.

Geopotential models; Global gravitational models; Potential coefficient models

Definition

A *Global Gravitational Model* (GGM) is a mathematical approximation to the external gravitational potential of an attracting body.

Gravitation is the term used to describe the potential generated by the masses of an attracting body like the Earth. *Gravity* is the term used for the potential of gravitation plus the centrifugal potential due to the rotation of the attracting body.

Global Gravitational Models

Introduction

A GGM is a mathematical approximation to the external gravitational potential of an attracting body. We will focus here on the case where the attracting body is the Earth, although many of the concepts that we discuss apply equally

well to other planets and celestial bodies. In its most complete and general form, a GGM consists of a set of numerical values for certain parameters, the statistics of the errors associated with these values (as described, e.g., by their error variance-covariance matrix), and a collection of mathematical expressions and algorithms that allow a user to perform:

1. *Synthesis*, that is, computation of the numerical values of quantities related to the gravitational potential (*functionals* of the gravitational field), given the position of the evaluation point.
2. *Error Propagation*, that is, computation of the expected errors of the computed functionals, as implied by the propagation of the errors of the parameters defining the GGM.

A GGM must be able to support such computations at arbitrary points, located on or above the Earth's surface, in a fashion that is both rigorous and efficient. In addition, a GGM should fulfill certain conditions stemming from the underlying physics. Namely, it should represent a scalar function of position that is harmonic outside the attracting masses and vanishes at infinity as the reciprocal of the distance between attracted point and attracting mass element. Moreover, the GGM should permit the computation of any functional of the field in a way that guarantees *self-consistency*. This

means that the model should preserve the relationships (differential or integral) between the various functionals. A GGM has numerous uses, both operational and scientific (see also [Tscherning 1983]), including:

1. Orbit determination applications necessary for space surveillance (the detection, tracking, and orbit prediction of Earth-orbiting objects).
2. Inertial navigation applications for trajectory determination of airplanes and missiles.
3. *Geoid* determination. The geoid is one of the infinitely many *level* (or *equipotential*) surfaces of the gravity field of the Earth, that is, the gravity potential is constant at every point on the geoid. The geoid is the specific equipotential surface that would coincide exactly with the mean ocean surface of the Earth, if the oceans were in equilibrium, at rest, and extended through the continents (such as with very narrow canals). Figure 1 shows the geoid surface that is implied by the EGM2008 GGM (Pavlis et al. 2008). Geoid determination allows one to transform a *geometric* (ellipsoidal) height to an *orthometric* one, that is, to an elevation referenced to an equipotential surface, as those elevations that appear on topographic maps. This application has attracted great interest in recent years, because GPS positioning and geoid determination offer the possibility of determining

Gravity, Global Models, Fig. 1 Geoid undulations (in meters), implied by the EGM2008 Global Gravitational Model, to degree 2,160, with respect to the WGS 84 reference ellipsoid

Gravity, Global Models, Fig. 2 Dynamic Ocean Topography (DOT) (in centimeters), obtained by subtracting the EGM2008 geoid undulations from a Mean Sea Surface grid computed at the Danish National

Space Center (DNSC). Notice the low associated with the Antarctic Circumpolar Current (ACC) and the highs associated with the Pacific Ocean gyres

orthometric heights and height differences without the need for the expensive and laborious spirit leveling (Schwarz et al. 1987).

4. Oceanographic applications that require the estimation of the Dynamic Ocean Topography (DOT), an estimate of which is shown in Fig. 2, and of its slopes. These quantities are directly related to ocean circulation. This application puts very stringent accuracy and resolution requirements on GGMs (Ganachaud et al. 1997).
5. An accurate and high-resolution GGM may be used to provide a reference surface – a global, high-resolution geoid surface – suitable for the realization of a global vertical datum (Rapp and Balasubramania 1992).
6. Geophysical prospecting applications where, in combination with other information (e.g., seismic data), a GGM may provide important constraints that aid the determination of the subsurface density distribution.
7. Comparisons of the decay of the spectrum of the gravitational potential to the decay of the spectrum of the Earth's topography (Rapp 1989).

These and other applications represent integral parts of various civilian and military activities. Each of these applications has (in general) different accuracy and resolution requirements, as far as the supporting GGM is concerned. For example, due to the attenuation of the gravitational field

with increasing altitude, a relatively low-resolution GGM (e.g., a *Spherical Harmonic Analysis Applied to Potential Fields* to maximum degree and order 70 or 90) is currently adequate for the precise orbit determination of most Earth-orbiting satellites. In contrast, accurate determination of the slopes of the equipotential surface (deflections of the vertical) demands a GGM of much higher resolution.

Geodesists have at various times developed “special purpose” GGMs that optimize performance for a particular application (e.g., orbit determination of a particular satellite, or geoid undulation computation over a specific geographic region). Although such “tailored” models have found some uses in the past, the ultimate goal has always been the development of a *single*, general purpose, GGM that addresses the different and diverse applications in an optimal manner, without over-performing in one application at the expense of its performance in others.

The development of a high-resolution GGM is a task that involves the optimal combination of a variety of data (satellite, land, marine, airborne). This is because a single data type with both global coverage and with uniformly high accuracy and high *spectral* sensitivity does not (yet) exist. The aforementioned data are of complementary character (in terms of spectral sensitivity and/or of geographic coverage), so that their optimal combination enables a GGM to satisfy the variety of applications described before.

Comprehensive GGM solutions that combine different types of data may involve the simultaneous estimation of the parameters that describe the gravitational potential, along with parameters that describe the dynamic ocean topography, solid Earth and ocean tides, Earth orientation and tracking station position parameters, as well as a plethora of “nuisance” parameters necessary to model completely the content of certain data types (e.g., biases and delays associated with certain satellite tracking data). The result of a successful GGM development effort is a model that can be used as a *standard* for numerous applications, over a substantial period of time.

Local and Regional Gravimetric Models

The accuracy and the resolving power of the data that were used in its development dictate the accuracy and resolution of a GGM. Geopolitical and/or proprietary data issues many times prevent the individual or the team developing a GGM from having access to *all* the existing data. However, over some regions, data of higher accuracy and/or resolving power (e.g., geographically dense sets of gravity and elevation data) may be available to some individual(s) or may become available *after* a GGM has been developed. These data may be used in combination with the existing GGM to improve the accuracy and/or resolution of the determination of *one or more specific functionals of the field*, over the region where the detailed data became available. This local or regional “densification” can produce a specific local or regional gravimetric product or model.

Such densification has been among the favorite geodetic activities over many decades now, and represents the geodesist’s way of creating a *multi-resolution* gravitational model resembling a “quilt.” In effect, patches of fine detail (the *Local Gravimetric Models* – LGMs) are sewn on top of a more or less homogeneous piece of fabric (the reference GGM). The GGM is the foundation upon which any regional or local gravimetric approximation study and application is built. Geodesists do not necessarily have to reevaluate the reference GGM every time a new set of data becomes available locally. Such reevaluation is mostly warranted if new and improved satellite data become available, spanning a sufficiently long time period, and/or if new terrestrial data (of higher accuracy and/or resolution) become available over areas with substantial geographic extent.

Signal Representation and Data Characteristics

Although geodesists have variously considered and studied the representation of the gravitational potential using *point masses* (Sünkel 1981, 1983), *finite element* methods (Meissl 1981; Baker 1988), and *splines* (Sünkel 1984; Jekeli 2005), these approaches have seen only limited application in the representation of (especially) the “static” (i.e., the time-averaged) gravitational field of the Earth. *Spherical harmonic*

functions have prevailed as the standard form used for the representation of the gravitational potential globally, from the very early days of global determinations to the present. Indeed, the set of coefficients of a *Spherical Harmonic Analysis Applied to Potential Fields* of the gravitational potential has become pretty much synonymous with a GGM.

Nerem, Jekeli, and Kaula (1995) provide a review of the gravity field determination process, including a review of global-scale modeling. Bouman (1997) provides a comprehensive “survey” of global gravity field models starting from the 1970s. Rapp (1998) provides a review of the geopotential modeling developments of the twentieth century, which includes an extensive list of references.

The Earth’s external gravitational potential, V , at a point P defined by its geocentric distance (r_P), geocentric colatitude (θ_P) (defined as 90° minus the geocentric latitude), and longitude (λ_P), can be expressed as:

$$V(r_P, \theta_P, \lambda_P) = \frac{GM}{r_P} \left[1 + \sum_{n=2}^{\infty} \left(\frac{a}{r_P} \right)^n \sum_{m=-n}^n C_{nm} Y_{nm}(\theta_P, \lambda_P) \right]. \quad (1)$$

GM is the geocentric gravitational constant (the product of the universal gravitational constant, G , times the mass of the Earth including its atmosphere, M) and a is a scaling factor associated with the fully normalized, unitless, spherical harmonic coefficients C_{nm} (a is usually numerically equal to the equatorial radius of an adopted mean-Earth ellipsoid). The absence of first-degree terms in Eq. 1 is a consequence of placing the origin of the coordinate system at the Earth’s center of mass. The *Spherical Harmonic Analysis Applied to Potential Fields* are defined as (Heiskanen and Moritz 1967, Sect. 1–14):

$$Y_{nm}(\theta_P, \lambda_P) = \bar{P}_{n|m|}(\cos \theta_P) \cdot \begin{cases} \cos m\lambda_P & \text{if } m \geq 0 \\ \sin |m| \lambda_P & \text{if } m \leq 0 \end{cases}. \quad (2)$$

$\bar{P}_{n|m|}(\cos \theta_P)$ is the fully-normalized associated legendre function of the first kind, of degree n and order $|m|$. The normalization of the surface spherical harmonic functions Y_{nm} is such that:

$$\frac{1}{4\pi} \int_{\sigma} Y_{nm}^2 d\sigma = 1, \quad (3)$$

where the integral is taken over the unit sphere σ , whose area element is $d\sigma$. In practice, the degree summation in Eq. 1 is truncated to some finite degree N , which defines (approximately) the resolution of the GGM. A useful rule of

thumb is that the half-wavelength linear resolution ($\lambda/2$), on the Equator, expressed in kilometers, is related to N by:

$$\lambda/2 = \frac{180^\circ}{N} \cdot 111 \text{ (km)}. \quad (4)$$

Figure 3 shows a representative example of the fine detail (high resolution) that can be captured with an expansion to degree 2,160, compared to the lower-resolution information that is retrievable using an expansion to degree 360. A spherical harmonic expansion complete to degree and order N involves $(N + 1)^2$ spherical harmonic coefficients, a number that grows rapidly as the maximum degree, and therefore the resolution of the model, increases. For example, an expansion to degree 360, as the EGM96 model involves $O(130 \text{ k})$ coefficients, while EGM2008, which extends to degree 2,160, involves approximately 4.7 million coefficients. The availability of efficient numerical algorithms for the estimation and for the subsequent use of these spherical harmonic expansions is obviously of critical importance. The goal of global high-resolution gravitational modeling is to estimate, as accurately as possible, the coefficients C_{nm} , to as high degree as possible, through the optimal combination of gravitational information from a variety of data sources. Of equal importance is the estimation of reliable error estimates for the C_{nm} values. The estimated C_{nm} values can then be used to compute functional(s) of the field (e.g., Geoid *undulations*, *gravity anomalies*, deflections of the vertical) while their associated errors (and error correlation when available) can

be propagated to yield the errors of the derived functional(s). Before the dawn of the new millennium and the availability of data from the satellite missions CHAMP, GRACE, and GOCE, four kinds of gravitational information were commonly available for the development of high-degree combination gravitational models like EGM96 (Lemoine et al. 1998):

1. Gravitational information obtained from the analysis of satellite orbit perturbations that are deduced from tracking data. This is of critical importance for the accurate determination of the low degree part of the model. *Satellite-only* models have progressed from solutions to degree 4 in the early 1960s, to models complete to degree 70 or 90 available by the end of the twentieth century. These advances were made through the availability of ever more accurate tracking data acquired over a continuously expanding constellation of Earth orbiters. Tracking data from approximately 40 satellites have been used in the development of the satellite-only solution supporting EGM96 (denoted EGM96S) (Lemoine et al. 1998). These data include optical, radio Doppler and radio interferometric observations, Satellite Laser Ranging (SLR), Doppler Orbit determination and Radiopositioning Integrated on Satellite (DORIS), and Satellite-to-Satellite Tracking (SST) data from the Global Positioning System (GPS) and Tracking and Data Relay Satellite System (TDRSS) constellations to lower Earth orbiters. Despite these advances, these tracking data types are incapable of resolving the fine

Gravity, Global Models, Fig. 3 Free-air gravity anomalies (in mGal, where $1 \text{ mGal} = 10^{-5} \text{ m/s}^2$) implied by two GGMs of different maximum degrees (different resolving powers), over the Yucatán Peninsula. EIGEN-GL04C extends to degree 360, while EGM2008 extends to

degree 2,160. The Chicxulub impact crater “ring” is clearly visible in the EGM2008 gravity anomalies, but cannot be discerned in the EIGEN-GL04C gravity anomalies due to the lower resolution of this model

Gravity, Global Models, Fig. 4 Free-air gravity anomalies (in mGal) implied by EGM2008 to degree 2,160, averaged over $5' \times 5'$ cells on the surface of the Earth. These values reveal numerous geophysical features, such as oceanic trenches, ridges, subduction and fracture zones, and

seamount chains. The lack of detailed data over Antarctica is also clearly evident from the smoothness of the values over this region (for the development of EGM2008, only GRACE satellite information was available over Antarctica)

structure of the field due to the attenuation of the gravitational signal with altitude. Moreover, the available satellites do not sample uniformly the range of orbital inclinations and altitudes, which is a necessary condition for the de-correlation of the harmonic coefficients estimated from satellite tracking data only. This causes strong correlation especially among coefficients of higher degrees within satellite-only solutions, and necessitates the use of a priori constraints in the development of satellite-only models (Lerch et al. 1979).

2. Surface (land, marine, and airborne) gravimetric data, which are (essentially) measurements of the magnitude of the acceleration of gravity. These data are in principle capable of resolving both long and short wavelength features of the gravity field. This, however, requires uniform global coverage with dense gravity data of uniformly high accuracy. The best available data sets ca. 1996 (Kenyon and Pavlis 1996) represent information derived from over 4,000 sources of detailed gravity data collected over several decades. The accuracy and density of point data vary substantially with geographic region, with extended regions (e.g., Antarctica) being practically void of gravity measurements. *Gravity Anomalies, Interpretation* values are the remainders after subtraction from the gravity measurements of the gravity acceleration

implied by an ellipsoidal reference (normal) field (see also Fig. 4). These gravity anomalies are susceptible to various systematic errors (Heck 1990). These errors, in conjunction with the nonuniformity of coverage, degrade the long wavelength integrity of the gravitational information that can be extracted from surface gravimetry. Nevertheless, surface and airborne gravimetry presently provide the only data that can resolve short wavelength gravity features, especially over land areas. In addition, shipborne gravity measurements may aid the separation of the geoid from the DOT signal when used in combination with satellite altimetry. The processing of surface gravity data also requires accurate and high-resolution information of the Earth's topography. This information is necessary both for the preprocessing of the gravity data and for the computation of correction terms that are necessary in order to determine the geoid surface over the continents, from the estimated GGM coefficients (Rapp 1997). It may also be used to supplement low-resolution gravitational information that may be available over certain geographic regions, with high-resolution information implied by the gravitational effects of the Earth's topography. This approach was used effectively for the development of EGM2008, as it is discussed by Pavlis et al. (2007).

3. Satellite altimeter data have enabled an unsurpassed mapping of the field over the oceans, in terms of both accuracy and resolution. TOPEX/Poseidon (T/P) (Fu et al. 1994) was the first satellite altimetry mission that routinely provided measurements of the Sea Surface Height (SSH), which were not significantly contaminated by radial orbit error (RMS radial orbit error at the ± 2 cm level). However, altimetric measurements are confined over the ocean areas bounded by the satellite's inclination, and furthermore provide a mapping of the sum of the geoid undulation (the height of the geoid surface with respect to the surface of an ellipsoid of revolution) plus the DOT. These aspects weaken somewhat the contribution of altimeter data in the determination of the long wavelength gravitational field and necessitate the appropriate modeling and estimation of the DOT when altimeter SSH data are used in combination solutions. There is, however, another way of incorporating altimeter data into a high-degree GGM, which is discussed next.
4. The combination of altimeter data from multiple missions (spanning several years), some of which have produced very closely spaced ground tracks, has provided a dense sampling of most of the ocean's surface. These data, in the form of SSH and/or SSH slopes, can be used to estimate ocean-wide sets of gravity anomalies, at very fine resolution (e.g., $2' \times 2'$ and even $1' \times 1'$). Spatial averages of these values can be "merged" with corresponding land and airborne gravity data and gravity information obtained from models of the potential generated by the topography and its *isostatic* compensation (Pavlis and Rapp 1990) to produce a complete global equiangular grid of gravity anomaly values. Figure 5 shows the identification of the data sources, which were used to compile the "merged"

$5' \times 5'$ free-air gravity anomaly data file that supported the development of EGM2008. The geometry of such a grid, in conjunction with the symmetry properties of the Legendre and the trigonometric functions, allows the applicability of very efficient harmonic analysis and *synthesis* methods (Rizos 1979; Colombo 1981a). These methods have revolutionized the development and use of very high-degree spherical harmonic expansions. These approaches also allow efficient combination with *satellite-only* information, as was done, for example, by Rapp and Pavlis (1990). However, incorporation of altimeter data into a GGM in this fashion requires some a priori knowledge of the DOT, so that the altimetry-derived gravity anomaly values are estimated from appropriately corrected SSH.

Satellite tracking, altimetric, and surface gravimetric data are of complimentary character both in a spectral as well as in a geographic sense. Their combination enables the determination of the gravitational field, over a wider band of its spectrum, with improved accuracy, than can be obtained by using any of the three data types alone. The particular means of combining these data, in order to develop a high-degree GGM, constitutes a solution strategy. A critical consideration in the design of a solution strategy is the treatment of altimeter data (Rapp 1993), that is, if these data will be incorporated as in (3) or as in (4) above. OSU91A (Rapp et al. 1991) and EGM96 (Lemoine et al. 1998) represent the result of implementing a particular solution strategy, whereby altimeter data were used as in (3) for the determination of the low degree part of these models (maximum degree 50 and 70, respectively), and as in (4) for the higher degree part. The OSU89A/B models (Rapp and Pavlis 1990) and the

Gravity, Global Models, Fig. 5 The major sources of free-air gravity anomaly data used to compile the "merged" file that supported the development of EGM2008. ArcGP stands for "Arctic Gravity Project," SIO/NOAA for "Scripps Institute of Oceanography/National Oceanic

and Atmospheric Administration," which provided the major portion of the altimetry-derived gravity anomalies. Fill-in values were computed by augmenting low-resolution gravitational information, by the high-resolution gravitational information implied by the topography

EGM2008 model (Pavlis et al. 2008) incorporated satellite altimeter data as in (4) above. Certain characteristics of the above data types that are particularly important for their effective combination are discussed next.

- *Information Content.* The observables within the above four categories contain information not only about the gravitational field, but also about numerous other effects. Some of these effects are of interest in their own right (e.g., the DOT information contained within altimetric SSH), while others represent, at least as far as gravitational modeling is concerned, systematic noise (e.g., the non-conservative forces acting on a satellite). In either case, effective incorporation of a particular data type into the combination solution requires precise modeling and optimal estimation of all the effects and signals contained within the observable. Otherwise, the estimated gravitational model can be severely corrupted by the mis-modeled (or unmodeled) systematic effects.
- *Spectral Sensitivity Overlap.* The development of a GGM through a *least squares adjustment* procedure combining different data types is meaningful, provided that the data used in the adjustment share some common degree of sensitivity to the gravitational signal over a certain portion of its spectrum (a range of harmonic degrees). Otherwise, there is little “adjustment” being performed to data representing disjoint spectral bands. For example, pre-GRACE satellite-only models have a narrow spectral sensitivity overlap with models recovered from surface gravity data alone. This complicated considerably the problem of optimal combination of these two data types. On the other hand, this also means that setting up and inverting extremely large linear systems corresponding to very high degree models may not be necessary, if a single data type (e.g., a complete global equiangular grid of gravity anomalies) uniquely determines the higher-degree portion of such a GGM.
- *Relative Weighting.* The optimal estimation of a GGM depends critically on the optimality of the relative weights assigned to the different data types. Considering the numerous sources of data that may be involved, this may

require the solution to a very large *component of variance* estimation problem, complicated further by the fact that the extraction of gravitational information from satellite orbit observations is a strongly nonlinear problem. Although approximate solutions to this relative weight estimation problem have been used with considerable success (Lerch 1991), many times the experience and intuition of the model developer(s) guide the selection of appropriate data weights more than anything else.

The Recent Gravity-Mapping Satellite Missions

The satellite data used for the development of all GGMs published by the end of the twentieth century represent tracking of “targets of opportunity,” that is, of spacecraft designed and equipped with instrumentation for applications other than the mapping of the gravitational field from space. As a result of three satellite missions, this situation has changed dramatically during the last decade. These three missions are CHAMP (Reigber et al. 1996), GRACE (GRACE 1998), and GOCE (ESA 1999). Table 1 summarizes the main characteristics of these missions.

A comprehensive discussion regarding the concepts involved in these three mission scenarios can be found in (ESA 1999, Sect. 2.3). Mapping of the gravitational field from space requires missions that adhere as much as possible to the following fundamental design constraints:

- Uninterrupted tracking in three spatial dimensions.
- Measurement or compensation of the effects of non-gravitational forces.
- Orbital altitude as low as possible, to enhance sensitivity to the gravitational signal, and inclination as high as possible, to permit (near) global coverage.
- Counteraction of the field’s attenuation at altitude through the measurement of derivatives of the potential.

All three missions have in common the high–low Satellite-to-Satellite Tracking component (SST-*hl*) from the GPS (and GLONASS in the case of GOCE) constellation, and the measurement of nongravitational forces by the onboard accelerometers. These data permit highly accurate orbit

Gravity, Global Models, Table 1 Main characteristics of three gravity-mapping satellite missions

Mission	Status	Orbit	Mission objective	Instrumentation, tracking, and comments
CHAMP	Launched on 7/15/2000 active	Alt. = 450 km $e \approx 0.004$ $i = 87^\circ$	Gravity and magnetic fields Atmospheric limb Sounding Ionosphere sounding	3-axis STAR accelerometer GPS and SLR altitude will decay from 450 km (BOL) to 300 km (EOL)
GRACE	Launched on 3/17/2002 active	Alt. = 485 km $e \approx 0.001$ $i = 89^\circ$	Gravity field and its temporal variation	3-axis accelerometers (1 per s/c) GPS and SLR K-band inter-satellite ranging between the 2 s/c
GOCE	Launched on 3/17/2009 active	Alt. ≈ 250 km $i = 96.7^\circ$ Sun-synchronous	Gravity field (Especially static)	Six 3-axis accelerometers forming the gradiometer GPS/GLONASS and SLR

determination for all three missions, and in addition may enhance the gravitational field determination at very long wavelengths (very low degrees). In addition to that, GRACE involves the continuous measurement of the range between two identical satellites that “chase each other,” which constitutes a low-low SST formation (SST-II). GOCE’s accelerometer array on the other hand provides the measurements necessary to determine the gravitational *tensor* (i.e., the 3×3 matrix of second-order spatial derivatives of the gravitational potential) at altitude. GOCE is unique in the sense that it will provide boundary data at altitude covering the entire Earth, *except* for two polar cap areas of $\sim 6.7^\circ$ radius (due to the satellite’s inclination). The data acquired by each of these three missions result in different sensitivities to the gravitational spectrum. Simulation studies examining the geopotential recovery attainable from these (and other) mission scenarios have been reported, for example, by Sneeuw and Ilk (1997). When considering the data from these satellite missions two main questions arise:

1. What is the optimal way of analyzing their data?
2. What is the optimal way of combining their data with existing data, for example, from surface gravimetry and from satellite altimetry, in order to develop high-degree combination gravitational models?

1. *Data Analysis.* In the case of CHAMP, the gravitational information is extracted from the analysis of the perturbations of a low Earth orbiter, in a fashion similar to other preexisting satellite missions. However, CHAMP’s low orbit, in conjunction with the accelerometer data and with the availability of nearly global tracking data coverage, enabled *for the first time* the determination of an accurate long wavelength global gravitational model from a *single* satellite’s data. Indicative of this “new state of affairs” was the fact that a very preliminary solution (complete to degree and order 91) was already developed based on a *single* month’s worth of CHAMP data *only* and was presented during the 2001 meeting of the International Association of Geodesy (IAG) by Reigber et al. (2001). Although significantly better models that include GRACE data have by now surpassed considerably this preliminary solution, it served as a good example of the improvements that were to follow.

Compared to CHAMP, GRACE added the SST-II component, which permitted higher-resolution gravitational information to be extracted from the analysis of the orbital perturbation *differences* along the line of sight of the two low orbiting satellites. One can use traditional orbit perturbation analysis methods to process the GRACE data and derive a GGM, for example, in spherical harmonics. GGM01S (Tapley et al. 2004) and GGM02S (Tapley et al. 2005) were estimated

following such a procedure. This analysis scenario, albeit costly, is within current computational capabilities for models extending to degree and order 180 or so. Geodesists have also considered alternative analysis methods for GRACE-type missions (e.g., Wolff 1969; Colombo 1981b; Jekeli 1999a; Rowlands et al. 2002). Such methods provide higher computational efficiency at the cost of introducing certain approximations. Setting aside for a moment the details of optimal GRACE data processing, it is important to recognize here the quantum leap that has been accomplished with the GRACE mission. Approximately 14 months of GRACE data *alone* have been used to develop GGM02S, whose cumulative global Root Mean Square (RMS) geoid undulation error to degree 70 is less than ± 1 cm (Tapley et al. 2005, Fig. 2). By comparison, the cumulative geoid undulation global RMS error to degree 70 for EGM96, which required the combination of data from tens of satellites, along with surface gravity and satellite altimetry, was ± 19 cm (Lemoine et al. 1998, Table 10.3.2-1).

As far as GOCE is concerned, numerous investigations of the various aspects of its data analysis and of the development of a GGM from them can be found in (ESA 2000). One particular issue that receives increased attention relates to the polar gaps and their impact on analysis schemes that exploit regularity and completeness in the data coverage.

2. *Data Combination.* While the existing satellite gravity-mapping missions (CHAMP and especially GRACE) have already delivered (or promise to deliver as in the case of GOCE) quantum leaps in the accuracy and resolution of the *satellite-only* gravitational models, there is still a need to combine that information with terrestrial gravity and satellite altimetry data in an optimal fashion. This is required so that a “seamless” extension of the gravitational spectrum can be achieved, taking advantage of the rich high frequency content of the surface and altimetric data. The higher resolution of GRACE-based and GOCE-based *satellite-only* models will significantly increase the spectral overlap with surface gravity and altimetry. This will enable for the first time the estimation of high-resolution models of the DOT as well as the significant reduction of systematic errors present in surface gravity data (see also [Pavlis 2000]).

Beyond the Sensitivity of Satellite Data

Due to the attenuation of the gravitational signal with increasing altitude, there is obviously a limit to the gravitational information that can be extracted from spaceborne sensors. This implies a limit to the resolution (maximum degree) of satellite-only models. Spectral estimation indicates that for

GRACE, the signal-to-noise ratio becomes one around degree 170, while for GOCE the corresponding degree is not expected to exceed 300. Observations made on the Earth's surface (or on airplanes flying at low altitudes) can extend the resolution of gravitational models considerably. Surface and airborne data like *gravity anomalies*, *gravity disturbances*, etc. are therefore capable of supporting the development of much higher resolution gravitational models than those developed based on satellite data only. One way of developing such high-degree models involves first the formation of a regular grid of spatially averaged values of some functional of the field that completely covers the globe. These values represent data derived on the basis of other primary observables, using techniques like *Least Squares Collocation* (LSC) (Moritz 1980). Surface gravity anomalies are a suitable choice for such a functional, both from a spectral sensitivity and from an availability viewpoint. Very high-degree and order spherical harmonic models are then developed from the analysis of such global anomaly grids, using efficient harmonic analysis techniques like those put forward by Colombo (1981a). Wenzel (1998, 1999) reported such expansions complete to degree and order 1800. Pavlis et al. (2005) reported the development and evaluation of the PGM2004A preliminary gravitational model, which combined GRACE information with a global set of $5' \times 5'$ gravity anomalies, and extended to maximum degree and order 2,160. The final product of that modeling effort was EGM2008 which also extends to degree 2,160 (Pavlis et al. 2008). EGM2008 was completed and released to the public in April 2008.

State-of-the-Art Global Gravitational Modeling

We briefly outline the main aspects of the development of two global gravitational models, representative of the state-of-the-art, given the data that were available, at the time of each model's development: EGM96 (Lemoine et al. 1998), which represents the state-of-the-art before the availability of data from the CHAMP and GRACE missions, and EGM2008 (Pavlis et al. 2008), which represents currently (March 2010) the model with the highest resolution and accuracy, prior to the anticipated availability of data from GOCE. A comparison of the approaches that were followed for the development of these two models reveals the critical changes in model development, which were brought about by the availability of GRACE data on one hand, and of high quality $5' \times 5'$ area-mean gravity anomalies (from the combination of terrestrial and altimetry-derived data sources) on the other.

In theory, the estimation of a GGM complete to some (arbitrary) high degree and order, from the combination of various (heterogeneous) data, could be carried out as follows:

- (a) Form separate normal equations from each individual data type, to a maximum degree and order that corresponds to the resolution of the available data and their sensitivity to the gravitational signal.
- (b) Treat satellite altimeter data as “direct tracking” observations, that is, ranges from the spacecraft to the ocean surface whose upper endpoint senses (through the orbit dynamics) attenuated gravitational signals (static and time varying), while their lower end point senses the combined effects of geoid undulation, DOT as well as tides and other time varying effects, without any attenuation. In this manner, altimeter data contribute to the estimation of the satellite's orbit, as well as the estimation of the DOT and of the potential coefficients.
- (c) Combine the various normal equations (with appropriate relative weights) and invert the resulting system, to estimate the combination solution to its high degree, along with its *full* error covariance matrix.

Such an “ideal” approach would permit the most rigorous modeling of the observables and would allow the greatest flexibility in terms of data weighting. A combination solution to degree 360, if performed as outlined above, would require the formation of full (symmetric) normal equation matrices (from satellite altimetry and surface gravimetry) for approximately 130,000 parameters (considering *only* the gravitational potential coefficients). For maximum degree 2,160, there would be approximately 4.7 million such parameters involved. Such computational tasks are beyond our present computational capabilities. Therefore, at present, one may choose between, or combine, two main solution strategies to attack the problem:

- *Solution Strategy (A)* Apply the “ideal” estimation strategy outlined above, to obtain a combination solution for the lower degree part of the field, up to a maximum degree that is computationally manageable. Apart from reasons of computational feasibility, this maximum degree should enable the appropriate modeling of the gravitational signal contained in the currently available satellite tracking data. Furthermore, since the DOT signal is of long wavelength nature, the benefits of “direct” altimetry are almost entirely retained here. To avoid aliasing effects however, the contribution to the altimetry and surface gravity data from the coefficients beyond the solved-for degree has to be filtered out of the data prior to the normal equation formation. This may be done using a preexisting high-degree solution (Pavlis 1988; Denker and Rapp 1990). Herein, we will refer to this type of solution as the *comprehensive* low-degree combination model. The obvious shortcomings of this approach are the relatively low maximum attainable degree (approximately 250 at present) and its computational demands. Some models developed using this approach (or similar ones) include JGM-1 and JGM-2 (Nerem et al. 1994) and JGM-3 (Tapley et al. 1996), the

part of EGM96 up to degree and order 70 (see Lemoine et al. 1998, Chap. 7), and EIGEN-GL04C (Förste et al. 2008).

- *Solution Strategy (B)* Consider that one is willing to make the following two approximations:
 1. The orbits of the altimeter satellites, whose data are included in the combination solution, are perfectly known (at least radially). This approximation is justifiable if one is working with altimeter satellites supported by T/P-class precise orbit determination. Moreover, after the availability of GRACE-based gravitational models for precise orbit determination of altimeter satellites, errors arising from gravitational model inaccuracies do not dominate the orbit error budget of these satellites. Errors due to, for example, mis-modeling of nonconservative forces acting on the spacecraft are likely to be more significant at present. In this regard, to allow the orbits of altimeter satellites to contribute (through their dynamics) to the determination of gravitational parameters within a combination solution may not be a desirable approach presently, because the effects of orbit errors of non-gravitational origin could corrupt the solved-for gravitational parameters.
 2. The DOT is known a priori, for example, from an Ocean Circulation Model (OCM) or from a previous low-degree comprehensive combination solution.

The implication of (1) is that satellite altimetry does not have to be treated as “direct” tracking anymore, which simplifies the problem considerably, since now orbit dynamics are not involved in the altimeter data processing. One is left with a “surface” problem, where the geoid (N) and the DOT (ζ) signals have to be separated, given the “observed” SSH (h), which is their sum. If in addition, the approximation (2) is introduced, then altimetry contributes to the combination solution “observed” geoid heights (N) over (parts of) the ocean.

In addition to the above two approximations, a key issue here is that altimetric information may also be provided in a *gridded* form. This is possible through the use of a Mean Sea Surface (MSS), obtained from multiple altimetric missions. The success of T/P has significantly improved the accuracy of MSS data sets (especially at long wavelengths). This is accomplished by adjusting the SSH data from other altimetric missions (e.g., ERS-1, ERS-2, GEOSAT, GEOSAT-Follow-On), to the surface defined by T/P, using crossover minimization techniques. Such MSS data sets have been developed by, for example, Yi (1995), Kim et al. (1995), Anzenhofer et al. (1996), Wang (2001), and more recently by Andersen and Knudsen (2009). One may also have available in *gridded* form, altimetry-derived gravity anomaly values. Such values have been estimated using various techniques, on an ocean-wide basis by, for example, Rapp and

Basic (1992), Andersen and Knudsen (1998), Andersen et al. (2010), Trimmer and Manning (1996) and Sandwell and Smith (1997, 2009) among others.

The two simplifying approximations discussed above and particularly the availability of altimetric information in gridded form (especially in the form of gravity anomalies) make applicable an alternative class of high-degree combination solution techniques. These techniques combine the satellite-only information, with potential coefficient information obtained from the analysis of *complete*, regular grids of functional(s) of the disturbing potential (e.g., N , Δg), and are based on the highly efficient harmonic analysis algorithms originally studied and put forward by Colombo (1981a). These algorithms exploit the regularity of the data grids and the symmetry properties of Legendre and trigonometric (sine/cosine) functions. Inherent in these algorithms is the use of Fast Fourier Transform (FFT) techniques to process data arrays residing over latitude bands that are symmetric with respect to the equator, in a highly efficient manner. Estimators of this type are the (simple) Numerical Quadrature (NQ), the Block-Diagonal (BD) least-squares adjustment, and the Optimal Estimation (OE) technique. Models developed using the NQ approach include OSU86E/F (Rapp and Cruz 1986a) and OSU89A/B (Rapp and Pavlis 1990). BD techniques of varying sophistication have been used to develop GPM2 (Wenzel 1985), DGF192A (Gruber and Bosch 1992), GFZ95A (Gruber et al. 1996), and EGM2008 (Pavlis et al. 2008). OE was used to develop the OSU86C/D models (Rapp and Cruz 1986b).

The two solution strategies (A) and (B) discussed above have their respective advantages and disadvantages. Due to computational limitations, the development of a GGM to spherical harmonic degree 360 or higher, currently requires the implementation of either a combination of the two strategies (as it was done for EGM96 and EIGEN-GL04C), or the implementation of strategy (B), as it was done for OSU89A/B and EGM2008. EGM96 (Lemoine et al. 1998) employed a comprehensive solution to degree 70, augmented by a BD solution from degree $n = 71$ to degree $n = 359$, while the $n = 360$ coefficients (which cannot be estimated using the BD technique) were obtained from an NQ model. The main reason for the choice of this solution strategy was the fact that the satellite-only component of EGM96 (denoted EGM96S), was accompanied by a variance-covariance matrix that was fully occupied. This was due to the fact that the heterogeneous tracking data from the (approximately) 40 satellites that were used to derive EGM96S to degree and order 70, were incapable of de-correlating adequately the spherical harmonic coefficients up to this degree and order. Therefore, in order to preserve the integrity of the least-squares adjustment used to combine EGM96S with the surface gravity and altimetry data, one had to consider the satellite-only normal equations in their complete (fully

occupied) form. Any block-diagonal approximation of these normal equations would result in estimation errors that could not be tolerated. This situation changed dramatically with GRACE, where the corresponding normal equation matrix, due to the global coverage and uniform GRACE data accuracy could be safely approximated by a block-diagonal matrix, without significant loss of accuracy. In addition, after the availability of satellite-only models from GRACE, there is really no need to incorporate altimeter data into the combination solution in the form of “direct” tracking. Instead, a preliminary model from GRACE and an MSS can be used to estimate a preliminary model of the DOT. This could then be used to correct the SSH of the MSS and estimate an ocean-wide set of altimetry-derived gravity anomalies. These can be “merged” with terrestrial and airborne data to form a complete global grid (see also Fig. 5). The gravitational information implied by these gridded data could then be combined (in a least-squares adjustment) with the satellite-only model from GRACE, to derive the combination solution, up to the high degree (2,160), in a single step. The entire process may be iterated, using the high-degree combination solution to derive the next estimate of the DOT, and so on. This is essentially the approach that was used to develop EGM2008 (Pavlis et al. 2008). Two iterations of the estimation of the altimetry-derived gravity anomalies were performed, which was

sufficient for the process to converge. Despite its iterative nature, this approach permits the development of very high-degree combination solutions in an efficient manner, and moreover in a single adjustment step, thereby avoiding the “piecewise” nature of models like EGM96.

Model Evaluation and Accuracy Assessment

Of central importance to the development of a GGM are the evaluation of its performance, and the estimation of reliable error measures to quantify its accuracy. The former requires the comparison of model-derived quantities to corresponding values obtained *independently*. Several different data types, withheld from a model’s development, are used for this purpose. These independent data have different spectral sensitivities and/or occupy different geographic regions. Tests that are usually employed here include satellite orbit determination and comparisons with tracking data, comparisons with geoid undulations obtained from GPS and leveling data, comparisons with deflections of the vertical obtained from astrogeodetic techniques (Jekeli 1999b), comparisons employing altimetry and general ocean circulation models, etc. A useful practice, introduced during the development of EGM96, and used also during the development of EGM2008, is to invite a voluntary evaluation working group, independent of a model’s developers, that evaluates and provides

Gravity, Global Models, Fig. 6 Propagated error estimates (in mGal) of the free-air gravity anomalies computed using the EGM2008 model. Notice the large error estimates over Antarctica and over mountainous areas (Himalaya, Andes), due to the lack of accurate and detailed data

Gravity, Global Models, Fig. 7 Propagated error estimates (in centimeters) of the geoid undulations computed using the EGM2008 model. The larger values around the equator are due to the lower density of GRACE data at low latitudes

feedback to the model's developers regarding candidate preliminary solutions, as well as the final outcome from a modeling effort, in a manner as objective as possible. These groups work under the auspices of the International Association of Geodesy (IAG) and upon completion of a certain evaluation effort they report their findings in IAG-sponsored publications, which can be accessed freely by the public. In the case of EGM2008, the results from such an evaluation by 25 different international investigating teams are reported in *Newton's Bulletin No. 4*, which is jointly published by the Bureau Gravimétrique International (BGI) and the International Geoid Service (IGeS).

The estimation of reliable errors that should accompany a model's derived quantities is also very important. These errors are geographically dependent, reflecting the different quality of the data used to develop the model, as a function of geographic area. For models like EGM2008, which involve a very large number of parameters (approximately 4.7 million), one cannot perform such error propagation using variance-covariance matrices and linear algebra methods, due to the excessively large sizes of the matrices involved. Instead, Pavlis and Saleh (2005) introduced and implemented an alternative approach that employs global convolutions with band-limited kernels. This technique is capable of providing very reliable error estimates, with geographic specificity, in a very efficient manner. Figures 6 and 7 illustrate geographically the propagated errors in free-air

gravity anomalies and in geoid undulations, implied by EGM2008 to degree 2,160.

Summary

Accurate knowledge of the gravitational potential of the Earth, on a global scale and at high resolution, is a fundamental prerequisite for various geodetic, geophysical, and oceanographic investigations and applications. Over the last 50 years, continuing improvements and refinements to the basic theory have been paralleled by the availability of more accurate and complete data and by dramatic improvements in the computational resources available for numerical modeling studies. These advances have brought the state-of-the-art from the early spherical harmonic models of degree 8 (Zhongolovich 1952) to solutions like EGM2008 that extends to degree 2,160. The availability of satellite missions like CHAMP, GRACE, and GOCE, dedicated to the mapping of the gravitational field from space, is enabling the determination of the long wavelength features of the field with unprecedented accuracy. Nevertheless, the determination of the fine details of the field still relies on the availability of terrestrial and airborne data, of high accuracy and sufficient geographic coverage and density. In this regard, several areas of the Earth, most notably Antarctica, await more comprehensive gravimetric surveying.

Gravity, Gradiometry

Christopher Jekeli

Division of Geodetic Science, School of Earth Sciences, Ohio State University, Columbus, OH, USA

Definition and Scope

Gravity gradiometry encompasses all manners of measuring the spatial gradients of the gravity vector field. In a broader sense, it includes the techniques for developing and applying gradient models, from both analytic and numerical perspectives, in order to validate gradient sensors, to study geologic bodies, and to test physical theories. Gravity gradiometry has a long and varied history of static (ground-based), shipborne, airborne, and spaceborne measurement systems. This entry includes the mathematical foundations and properties of gradients starting with Newton's law of gravitation. A description of straightforward modeling is followed by a rudimentary measurement error analysis; and the entry concludes with a comprehensive account of measurement systems, as well as some sample applications.

Introduction

Gravity gradiometry is over 120 years old, and it offers a rich perspective of the Earth's external gravitational field as generated by its crustal mass density structure. Like the measurement of gravity, gradiometry is used to make both qualitative and quantitative interpretations of the Earth's near subsurface interior. The spatial gradients of the Earth's gravity acceleration vector form a tensor of nine elements, three components for each of the three gravity vector components. They emphasize the fine structure and the short-wavelength characteristics of the field. They are largest over sharp subsurface geologic contrasts, such as faults, the edges of salt domes and igneous intrusions, and the flanks of synclines and anticlines. As the second derivatives of the gravity potential, the gravity gradients describe the curvature of the potential, and values of the differential curvature help to indicate directions of principal axes of source bodies. Gravity gradiometry also plays a significant role in understanding the fundamental nature of gravitation from a cosmological viewpoint.

While popular in the early part of the twentieth century to aid in the exploration for oil and gas, static gravity gradiometry has largely been replaced by scalar gravimetry (measurements of the magnitude of the gravity vector), both in the static mode and on airborne platforms, due to its greater efficiency and yet comparable accuracy. Gradiometry has resurfaced recently because for moving-base systems (e.g., aircraft and satellites), it is arguably the preferred type of

measurement since it does not require an independent system that determines the kinematic accelerations of the vehicle with equal precision, as does the gravimeter due to the principle of equivalence between inertial and gravitational mass.

Either the static or moving-base measurement of gradients requires exquisitely sensitive instrumentation, which over these last 120 years has improved less in accuracy than in resolution (integration time) for the surface and airborne systems. Typical airborne systems today advertise the same precision that the static instruments had at the beginning of the twentieth century. However, they have a much higher temporal resolution (of the order of a few seconds) compared to the many hours required for the early static instruments. On the other hand, the recent launch of a satellite-borne gradiometer represents a major advance in global gradiometry with an accuracy improvement of one to two orders of magnitude, but at the expense of sensing the field in the relatively far removed (from the sources), but dynamically quiet environment of space. Because of the relatively great expense of current gradiometer technology, to date only a few terrestrial (airborne and shipborne) systems are in operation.

The following sections cover the basic theory of gravitational gradients, the history of the sensor technology from the first torsion balance to modern-day gradiometers, the forward modeling of gravitational gradients, and applications in geodesy, geophysics, and physics.

Mathematical Foundations

Gravitational Gradients

Newtonian gravitational field theory adequately serves both to develop the necessary field equations, their solutions, and the derivation and use of gravitational gradients. No attempt is made or needed for present purposes to discuss the gradients in terms of Einstein's theory of general relativity. One may start with Newton's law of gravitation that posits the force between two point masses as proportional to each of the masses, inversely proportional to the square of the distance between them, and directed along the connecting line. An equivalent concept is the Newtonian gravitational field potential that quantifies the work (energy) needed to bring a unit test mass from a position, $\mathbf{x}$, to infinity for a given attracting point mass, m , located at $\mathbf{x}'$,

$$V(\mathbf{x}) = \frac{Gm}{|\mathbf{x} - \mathbf{x}'|}, \quad (1)$$

where G is Newton's gravitational constant and the geophysical convention of positive potential is used. By the law of superposition, the potential is generalized by summation to a discrete set of mass points and, ultimately, using the concept of mass density, $\rho = dm/dv$, to (piecewise) continuous distributions of mass,

$$V(\mathbf{x}) = G \int_v \frac{\rho(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} dv, \quad (2)$$

where v is the region in space occupied by the mass density. The potential of a volume distribution is a differentiable (hence also continuous) function for all points inside and outside v and on its boundary.

The spatial gradient of the gravitational potential is the gravitational acceleration (gravitation) experienced by the test mass at $\mathbf{x}$,

$$\mathbf{g}(\mathbf{x}) = \nabla V(\mathbf{x}). \quad (3)$$

The spatial gradient of the components of the gravitation vector constitutes the elements of the gravitational gradient tensor,

$$\mathbf{\Gamma}(\mathbf{x}) = \nabla \nabla^T V(\mathbf{x}) = \nabla \mathbf{g}^T(\mathbf{x}), \quad (4)$$

where “T” denotes the transpose of a vector (or matrix). In Cartesian coordinates, $\mathbf{x} = (x_1, x_2, x_3)^T$, the gravitational gradient tensor is given by

$$\begin{aligned} \mathbf{\Gamma} &= \begin{pmatrix} \frac{\partial^2 V}{\partial x_1^2} & \frac{\partial^2 V}{\partial x_1 \partial x_2} & \frac{\partial^2 V}{\partial x_1 \partial x_3} \\ \frac{\partial^2 V}{\partial x_2 \partial x_1} & \frac{\partial^2 V}{\partial x_2^2} & \frac{\partial^2 V}{\partial x_2 \partial x_3} \\ \frac{\partial^2 V}{\partial x_3 \partial x_1} & \frac{\partial^2 V}{\partial x_3 \partial x_2} & \frac{\partial^2 V}{\partial x_3^2} \end{pmatrix} \\ &= \begin{pmatrix} \frac{\partial g_1}{\partial x_1} & \frac{\partial g_2}{\partial x_1} & \frac{\partial g_3}{\partial x_1} \\ \frac{\partial g_1}{\partial x_2} & \frac{\partial g_2}{\partial x_2} & \frac{\partial g_3}{\partial x_2} \\ \frac{\partial g_1}{\partial x_3} & \frac{\partial g_2}{\partial x_3} & \frac{\partial g_3}{\partial x_3} \end{pmatrix} = \begin{pmatrix} \Gamma_{1,1} & \Gamma_{1,2} & \Gamma_{1,3} \\ \Gamma_{2,1} & \Gamma_{2,2} & \Gamma_{2,3} \\ \Gamma_{3,1} & \Gamma_{3,2} & \Gamma_{3,3} \end{pmatrix}. \end{aligned} \quad (5)$$

The tensor is symmetric and exists where the potential is twice differentiable.

Poisson’s field equation characterizes a Newtonian gravitational field through its second-order gradients, specifically by the trace of the gravitational gradient tensor,

$$\nabla \cdot \nabla V(\mathbf{x}) = \nabla^2 V(\mathbf{x}) = -4\pi G \rho(\mathbf{x}), \quad (6)$$

where the Laplacian operator in Cartesian coordinates is

$$\nabla^2 = \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} + \frac{\partial^2}{\partial x_3^2}. \quad (7)$$

Equation (6) shows that the gradient does not exist at discontinuities of the mass density, such as at the exact interface between the solid Earth and atmosphere. By its symmetry

and Poisson’s equation, the gravitational gradient tensor has only five independent elements for points where the mass density distribution is known. For later reference, the potential in free space satisfies Laplace’s equation,

$$\nabla^2 V(\mathbf{x}) = 0. \quad (8)$$

If a local coordinate system has its three-axis aligned with the vertical, positive downward, and the one-axis points northward, then the horizontal rate of change of the vertical component of gravitation, g_3 , is called the horizontal gradient, with magnitude and direction of greatest variation (from north), respectively, given by

$$\Gamma_H = \sqrt{\Gamma_{1,3}^2 + \Gamma_{2,3}^2}, \quad \alpha_H = \tan^{-1} \frac{\Gamma_{2,3}}{\Gamma_{1,3}}. \quad (9)$$

Gravitational gradients also describe the curvature of a surface of constant gravitational potential (a level surface) (Fig. 1). Let $\rho_{1'}$ and $\rho_{2'}$ be the two principal radii of curvature at a point on the surface, whose reciprocals are, respectively, the minimum and maximum curvatures along corresponding (orthogonal) axes, $x_{1'}$ and $x_{2'}$. It can be shown (Heiland 1940; Nettleton 1976) that the differential curvature, $\Delta\kappa = g_3(1/\rho_{2'} - 1/\rho_{1'})$, is given by

$$\Delta\kappa = \sqrt{(2\Gamma_{1,2})^2 + (\Gamma_{2,2} - \Gamma_{1,1})^2}. \quad (10)$$

The direction of minimum curvature is

$$\alpha_c = \frac{1}{2} \tan^{-1} \frac{-2\Gamma_{1,2}}{\Gamma_{2,2} - \Gamma_{1,1}}. \quad (11)$$

Gravity, Gradiometry, Fig. 1 Principal radii of curvature at a point on an equipotential surface

Gravity, Gradiometry,**Fig. 2** Local Cartesian coordinates relative to (a) spherical polar coordinates and (b) ellipsoidal (spheroidal) coordinates

If $a_c = 0$, then the local coordinate axes, x_1 and x_2 , coincide with the directions of minimum and maximum curvature; and $\Gamma_{1,2} = 0$. In general, we also have

$$\begin{aligned}\Gamma_{2,2} - \Gamma_{1,1} &= g_3(1/\rho_{2'} - 1/\rho_{1'}) \cos 2\alpha_c, \\ \Gamma_{1,2} &= -\frac{1}{2}g_3(1/\rho_{2'} - 1/\rho_{1'}) \sin 2\alpha_c.\end{aligned}\quad (12)$$

Other Coordinate Systems

For a local Cartesian coordinate system embedded in a spherical polar coordinate system as shown in Fig. 2a, the first- and second-order derivatives are related to corresponding derivatives with respect to the spherical coordinates, as follows,

$$\frac{\partial}{\partial x_1} = -\frac{1}{r} \frac{\partial}{\partial \theta}, \quad \frac{\partial}{\partial x_2} = \frac{1}{r \sin \theta} \frac{\partial}{\partial \lambda}, \quad \frac{\partial}{\partial x_3} = -\frac{\partial}{\partial r}; \quad (13)$$

$$\begin{aligned}\frac{\partial^2}{\partial x_1^2} &= \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \theta^2} \\ \frac{\partial^2}{\partial x_1 \partial x_2} &= \frac{\cot \theta}{r^2 \sin \theta} \frac{\partial}{\partial \lambda} - \frac{1}{r^2 \sin \theta} \frac{\partial^2}{\partial \theta \partial \lambda} \\ \frac{\partial^2}{\partial x_1 \partial x_3} &= -\frac{1}{r^2} \frac{\partial}{\partial \theta} + \frac{1}{r} \frac{\partial^2}{\partial \theta \partial r} \\ \frac{\partial^2}{\partial x_2^2} &= \frac{\cot \theta}{r^2} \frac{\partial}{\partial \theta} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2}{\partial \lambda^2} \\ \frac{\partial^2}{\partial x_2 \partial x_3} &= \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \lambda} - \frac{1}{r \sin \theta} \frac{\partial^2}{\partial \lambda \partial r} \\ \frac{\partial^2}{\partial x_3^2} &= \frac{\partial^2}{\partial r^2}\end{aligned}\quad (14)$$

with corresponding Laplacian operator,

$$\begin{aligned}\nabla^2 &= \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} + \frac{\partial^2}{\partial x_3^2} \\ &= \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \theta^2} + \frac{\cot \theta}{r^2} \frac{\partial}{\partial \theta} + \frac{1}{r^2 \sin^2 \theta} \\ &\quad \times \frac{\partial^2}{\partial \lambda^2}.\end{aligned}\quad (15)$$

Usually the Earth is approximated by an oblate rotational ellipsoid (spheroid) generated by rotating an ellipse with linear eccentricity, E , about its semi-minor axis, identified as the polar axis. Corresponding ellipsoidal (spheroidal) coordinates, (u, δ, λ) , are shown in Fig. 2b, where surfaces of constant u are confocal ellipsoids and surfaces of constant δ are hyperboloids of revolution of one sheet. As for spherical coordinates, surfaces of constant longitude, λ , are half-planes containing the polar axis. The local first- and second-order derivatives with respect to Cartesian coordinates (where the local x_3 -axis is orthogonal to the confocal ellipsoid that passes through the origin of the local system) are related to the corresponding derivatives with respect to the ellipsoidal coordinates, as follows,

$$\begin{aligned}\frac{\partial}{\partial x_1} &= -\frac{1}{w} \frac{\partial}{\partial \delta}, \quad \frac{\partial}{\partial x_2} = \frac{1}{v \sin \delta} \frac{\partial}{\partial \lambda}, \quad \frac{\partial}{\partial x_3} \\ &= -\frac{w}{v} \frac{\partial}{\partial u};\end{aligned}\quad (16)$$

$$\begin{aligned}\frac{\partial^2}{\partial x_1^2} &= \frac{1}{w^2} \left(\frac{uv^2}{w^2} \frac{\partial}{\partial u} + \frac{E^2 \sin 2\delta}{2w^2} \frac{\partial}{\partial \delta} + \frac{\partial^2}{\partial \delta^2} \right) \\ \frac{\partial^2}{\partial x_1 \partial x_2} &= \frac{1}{wv \sin \delta} \left(\cot \delta \frac{\partial}{\partial \lambda} - \frac{\partial^2}{\partial \delta \partial \lambda} \right) \\ \frac{\partial^2}{\partial x_1 \partial x_3} &= \frac{v}{w^2} \left(-\frac{u}{w^2} \frac{\partial}{\partial \delta} + \frac{E^2 \sin 2\delta}{2w^2} \frac{\partial}{\partial u} + \frac{\partial^2}{\partial \delta \partial r} \right) \\ \frac{\partial^2}{\partial x_2^2} &= \frac{\cot \delta}{w^2} \frac{\partial}{\partial \delta} + \frac{u}{w^2} \frac{\partial}{\partial u} + \frac{1}{v^2 \sin^2 \delta} \frac{\partial^2}{\partial \lambda^2} \\ \frac{\partial^2}{\partial x_2 \partial x_3} &= \frac{1}{w \sin \delta} \left(\frac{u}{v^2} \frac{\partial}{\partial \lambda} - \frac{\partial^2}{\partial \lambda \partial u} \right) \\ \frac{\partial^2}{\partial x_3^2} &= \frac{1}{w^2} \left(-\frac{E^2 \sin 2\delta}{2w^2} \frac{\partial}{\partial \delta} - \frac{uE^2 \sin^2 \delta}{w^2} \frac{\partial}{\partial u} + v^2 \frac{\partial^2}{\partial u^2} \right)\end{aligned}\quad (17)$$

where

$$v^2 = u^2 + E^2, \quad w^2 = u^2 + E^2 \cos^2 \delta. \quad (18)$$

The Laplacian operator is

$$\nabla^2 = \frac{1}{w^2} \times \left(v^2 \frac{\partial^2}{\partial u^2} + 2u \frac{\partial}{\partial u} + \frac{\partial^2}{\partial \delta^2} + \cot \delta \frac{\partial}{\partial \delta} + \frac{w^2}{v^2 \sin^2 \delta} \frac{\partial^2}{\partial \lambda^2} \right). \quad (19)$$

Invariants

Being a second-order tensor, the gradients change under a rotation of Cartesian coordinates from system s to system t according to $\mathbf{\Gamma}^t = \mathbf{C}_s^t \mathbf{\Gamma}^s \mathbf{C}_t^s$, where $\mathbf{C}_s^t$ is the matrix of appropriate direction cosines. For any arbitrary Cartesian system, s , there exists a rotation that diagonalizes the tensor, $\mathbf{\Gamma}^s$,

$$\begin{pmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{pmatrix} = \mathbf{\Gamma}^t = \mathbf{C}_s^t \mathbf{\Gamma}^s \mathbf{C}_t^s. \quad (20)$$

The diagonal elements, λ_j , are the eigenvalues of $\mathbf{\Gamma}^s$, or any rotation thereof and are called invariants of the tensor with respect to coordinate rotations. They are real numbers because the tensor is real and symmetric. All combinations of eigenvalues are also invariants.

Given the tensor, $\mathbf{\Gamma}$, in some coordinate system, the eigenvalues are roots to the following characteristic equation ($\det$ = determinant),

$$\begin{aligned} \det(\lambda \mathbf{I} - \mathbf{\Gamma}) &= (\lambda - \lambda_1)(\lambda - \lambda_2)(\lambda - \lambda_3) \\ &= \lambda^3 - I_0 \lambda^2 + I_1 \lambda - I_2 = 0, \end{aligned} \quad (21)$$

from which it is easy to show that, with the gradient elements as designated in Eq. (5),

$$I_0 = \lambda_1 + \lambda_2 + \lambda_3 = \Gamma_{1,1} + \Gamma_{2,2} + \Gamma_{3,3}, \quad (22)$$

$$\begin{aligned} I_1 &= \lambda_1 \lambda_2 + \lambda_2 \lambda_3 + \lambda_3 \lambda_1 \\ &= \Gamma_{1,1} \Gamma_{2,2} + \Gamma_{2,2} \Gamma_{3,3} + \Gamma_{1,1} \Gamma_{3,3} - \Gamma_{1,2}^2 - \Gamma_{2,3}^2 \\ &\quad - \Gamma_{3,1}^2, \end{aligned} \quad (23)$$

$$I_2 = \lambda_1 \lambda_2 \lambda_3 = \det \mathbf{\Gamma}; \quad (24)$$

and, therefore, these quantities are invariants with respect to rotation. For example, Poisson's Eq. (6) implies $I_0 = -4\pi G\rho$.

From Eqs. (22) and (23), we have $I_0^2 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2 + 2I_1$. If $I_0 = 0$ (e.g., above the Earth's surface, neglecting the atmosphere), then $I_1 < 0$. Pedersen and Rasmussen (1990) show that

$$0 \leq I \equiv -\left(\frac{I_2}{2}\right)^2 / \left(\frac{I_1}{3}\right)^3 \leq 1; \quad (25)$$

and call I an indicator of two-dimensionality. $I = 1$ implies that the source of the gradients is like a monopole and $I = 0$ implies that the generated field is invariant in some direction, which means that the source is two-dimensional and can be described by a cross section.

Finally, we note that both Γ_H (Eq. 9) and $\Delta\kappa$ (Eq. 10) are horizontal invariants, that is, independent of the azimuthal orientation of the local frame.

Models and Modeling

As is quantified later in this section, the gravitational gradients, being second-order derivatives of the potential, reflect primarily the short-wavelength, local features of the Earth's crust. For this reason the forward modeling of gradients due to sources has largely concentrated on formulating the gradient signals of polyhedra of constant density, which by suitable assemblage can simulate the local crust, specifically the local topography. Given a regular distribution of elevation data for a particular region, the topography may be modeled as a collection of right rectangular prisms whose vertical dimension is defined by the elevation of a data point and whose base has dimensions equal to the horizontal resolution of the data. Other options to model the topography include triangular prisms (using a triangulation of the elevation data) and any of several numerical integration methods applied to (from Eq. 2)

$$\Gamma_{j,k}(\mathbf{x}) = G \int_V \rho(\mathbf{x}') \frac{\partial^2}{\partial x_j \partial x_k} \frac{1}{|\mathbf{x} - \mathbf{x}'|} dv. \quad (26)$$

The purposes of modeling gravitational gradients range from validation of gradiometer accuracy to introducing constraints on the geophysical inverse problem. As new gradiometer systems are developed, particularly airborne systems, determining their accuracy is aided by flying over regions with well-known topographic elevations and density contrasts. Comparing the measurements to gradients, forward-modeled from the topography, calibrates the noise level and enables tuning of appropriate data filters. Conversely, detecting subsurface geologic features, such as kimberlites (for diamond prospecting), from gradiometric surveys is facilitated by knowing what to look for in terms of a particular gradient signature. Thus, even in the inversion of gradiometric data to infer sources, forward modeling of structures plays an important role.

The gradients generated by constant-density, right-rectangular prisms follow from Eq. (26). If the prism has dimensions bounded by Cartesian coordinates, $a_1 \leq x'_1 \leq a_2$, $b_1 \leq x'_2 \leq b_2$, $c_1 \leq x'_3 \leq c_2$, the gradients for points outside the prism are given by

$$\Gamma_{jk}(\mathbf{x}) = -G\rho \ln(x_\ell - x'_\ell + r) \Big|_{x'_1=a_1}^{a_2} \Big|_{x'_2=b_1}^{b_2} \Big|_{x'_3=c_1}^{c_2}, \quad (27)$$

$$\Gamma_{jj}(\mathbf{x}) = G\rho \tan^{-1} \frac{(x_k - x'_k)(x_\ell - x'_\ell)}{(x_j - x'_j)r} \Big|_{x'_1=a_1}^{a_2} \Big|_{x'_2=b_1}^{b_2} \Big|_{x'_3=c_1}^{c_2}, \quad (28)$$

where $r^2 = (x_1 - x'_1)^2 + (x_2 - x'_2)^2 + (x_3 - x'_3)^2$ and where (j, k, ℓ) is a cyclic permutation of $(1, 2, 3)$. Using these formulas to model the gradients associated with the local topography is analogous to a numerical integration of Eq. (26) using the rectangular rule.

To take advantage of various other numerical integration techniques based on a discretization of the topographic surface, $h(x'_1, x'_2)$, over an area, A , one first integrates Eq. (26) with respect to the vertical, x'_3 ,

$$\begin{aligned} \Gamma_{jk}(\mathbf{x}) &= G\rho \iint_A T_{jk}(\mathbf{x}; x'_1, x'_2) dA \\ &\approx G\rho \sum_{i_1} \sum_{i_2} T_{jk}(\mathbf{x}; (x_1)_{i_1}, (x_2)_{i_2}) \Delta A_{i_1, i_2}, \end{aligned} \quad (29)$$

where the functions,

$$T_{jk}(\mathbf{x}; x'_1, x'_2) = \int_0^{h(x'_1, x'_2)} \frac{\partial^2}{\partial x_j \partial x_k} \left(\frac{1}{r} \right) dx'_3, \quad (30)$$

have well-defined analytic expressions (Jekeli and Zhu 2006). The discretization indicated by Eq. (29) then may take any number of forms.

For example, it may also be desirable to express $T_{j,k}$ as a Taylor series in h , in which case Eq. (29) becomes a series of two-dimensional convolutions on the plane,

$$\Gamma_{jk}(\mathbf{x}) = G\rho \iint_A \left(\sum_n \frac{1}{n!} \frac{\partial^n}{\partial h^n} T_{jk}|_{h=0} h^n \right) dx'_1 dx'_2, \quad (31)$$

where it is noted that the derivatives of $T_{j,k}$ are functions of $x_1 - x'_1$ and $x_2 - x'_2$ (besides x_3 and h). Discretized, such convolutions can be evaluated rapidly using fast algorithms for the discrete Fourier transform (Forsberg 1985), provided the variable, x_3 , remains constant (which is a limitation of the method). Similar Fourier transform methods have also been developed by (Parker 1972), but found to be less suitable (Jekeli and Zhu 2006) due to the use of the *analytic* Fourier transforms of the kernel functions, $\partial^n T_{j,k} / \partial h^n$. While the

linear term in the Taylor series may suffice in some cases, high-order expansions are required when evaluating the gradients near Earth's surface. Nonlinear effects are significant even for the problem of inverting gradients on the ocean surface to infer seafloor topography at depths of several kilometers (Yang et al. 2018).

Other fast methods transform the volume integral (Eq. 26) to surface and line integrals along the theory of Gauss (divergence theorem, etc.); Petrovic (1996) and Tsoulis and Petrovic (2001) have developed corresponding formulas for arbitrary polyhedra. In all these cases, the underlying coordinate system is Cartesian. Forward modeling of gravitational gradients in spherical coordinates that account for the convergence of coordinate lines of a data grid, as well as the convergence of radial (height) lines, has not received much attention (however, see Smith et al. 2001), since the gradients are influenced primarily by very local topography.

Spectral models of the gravitational gradients can be derived directly from corresponding models of the gravitational potential in local regions, as well as for the entire Earth; such global models exist in abundance as compiled, for example, by the International Center for Global Earth Models. The latter global models invariably represent the gravitational potential, V , in a series of solid spherical harmonic functions, $(R/r)^{n+1} \bar{Y}_{n,m}(\theta, \lambda)$, whose projections onto a sphere of radius, $r = R$, comprise the basis functions for the Fourier-Legendre spectrum, $\{(GM/R)C_{n,m}\}$, of the potential on that sphere. Extended into free space, $r \geq R$, the potential satisfies Laplace's Eq. (8) and is thus modeled according to

$$V(r, \theta, \lambda) = \frac{GM}{R} \sum_{n=0}^{\infty} \sum_{m=-n}^n \left(\frac{R}{r} \right)^{n+1} C_{n,m} \bar{Y}_{n,m}(\theta, \lambda), \quad (32)$$

assuming no masses exist outside the sphere of radius, R , and total mass, M . The (surface) spherical harmonic functions are defined by

$$\bar{Y}_{n,m}(\theta, \lambda) = \bar{P}_{n,|m|}(\cos \theta) \begin{cases} \cos m\lambda, & m \geq 0 \\ \sin |m|\lambda, & m < 0 \end{cases} \quad (33)$$

where the functions, $\bar{P}_{n,m}$, are associated Legendre functions of the first kind, fully normalized so that

$$\begin{aligned} &\frac{1}{4\pi} \iint_{\Omega} \bar{Y}_{n',m'}(\theta, \lambda) \bar{Y}_{n,m}(\theta, \lambda) d\Omega \\ &= \begin{cases} 1, & n' = n \text{ and } m' = m \\ 0, & n' \neq n \text{ or } m' \neq m \end{cases} \end{aligned} \quad (34)$$

and where Ω represents the unit sphere; see also (Jekeli 2017) for further details.

Practically, a spherical harmonic model is given with a limited spectrum up to maximum degree, $n_{\max}$. The gradients, $\Gamma_{j,k}$, corresponding to this model in a local coordinate system, as shown in Fig. 2a, can then be determined using Eq. (14). However, the spectrum with respect to the surface spherical harmonics does not exist for all the gradients. Specifically, any of the derivatives in latitude destroys the orthogonality of the basis (eigen-) functions on the sphere. It is easy to see, however, that the second radial derivative possesses a Fourier-Legendre spectrum.

Similarly, for a given ellipsoidal harmonic model with coefficients, $C_{n,m}^e$ (Jekeli 1988a),

$$V(u, \delta, \lambda) = \frac{GM}{R} \sum_{n=0}^{\infty} \sum_{m=-n}^n \frac{\bar{Q}_{n,|m|}(iu/E)}{\bar{Q}_{n,|m|}(ib/E)} C_{n,m}^e \bar{Y}_{n,m}(\delta, \lambda), \quad (35)$$

where $\bar{Q}_{n,m}$ is the fully normalized associated Legendre function of the second kind, the gradients in a local coordinate system are obtained using the derivatives in Eq. (17). Again, derivatives of the potential with respect to the ellipsoidal coordinate, δ , do not have a Fourier-Legendre spectrum with respect to the eigenfunctions, $\bar{Y}_{n,m}(\delta, \lambda)$. Although the second derivative with respect to the ellipsoidal coordinate, u , could be interpreted to have a Fourier-Legendre spectrum on a confocal ellipsoid with respect to the functions, $\bar{Y}_{n,m}(\delta, \lambda)$, it is not directly related to the local gradient, $\partial^2 V / \partial x_3^2$.

A representation of the potential and its derivatives using locally supported basis functions on the sphere has found particular application for gravitational gradients due to their inherently local spectral content (Eicker et al. 2014). In particular, the geopotential models constructed with radial basis functions (RBFs) (Freeden et al. 1998; Schmidt et al. 2007) have the form,

$$V(r, \theta, \lambda) = \sum_{k=1}^N c_k B_k(r, \theta, \lambda), \quad (36)$$

where the k^{th} RBF is

$$B_k(r, \theta, \lambda) = \sum_{n=0}^{n'} (2n+1) \left(\frac{R}{r}\right)^{n+1} B_n P_n(\cos \psi_k), \quad (37)$$

with spectral tuning coefficients, B_n , and central angle, ψ_k (the “radial” distance), from the central node, (θ_k, λ_k) , of its “local” support,

$$\cos \psi_k = \cos \theta \cos \theta_k + \sin \theta \sin \theta_k \cos(\lambda - \lambda_k). \quad (38)$$

In general, these RBFs still have global support, but with appropriate definition of their spectrum, they can be defined to

vanish outside local regions (Schreiner 1997). This leads then to spherical spline and wavelet representations of the gravitational potential on and external to the sphere. In each case the local gravitational gradients (i.e., in a local Cartesian coordinate system) are determined according to (14).

Usually, a local Cartesian coordinate system suffices to model the Fourier spectrum of the gradients. In this case, the spectra of all gradients may be derived from the spectrum of the potential. Starting with the representation of the potential in terms of its Fourier spectrum, $v(f_1, f_2)$, on a plane ($x_3 = 0$) and including the harmonic extension into free space ($-x_3 > 0$ in the north-east-down system), we have

$$V(x_1, x_2, x_3) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} v(f_1, f_2) e^{-2\pi f |x_3|} e^{i2\pi(f_1 x_1 + f_2 x_2)} df_1 df_2, \quad (39)$$

where $f = \sqrt{f_1^2 + f_2^2}$ and f_1, f_2 are spatial, cyclical frequencies. The Fourier spectrum, $\mathcal{G}$, of each gravitational gradient on the $|x_3|$ -plane is obtained by applying the appropriate derivative,

$$\begin{aligned} \mathcal{G}_{1,1}(f_1, f_2; x_3) &= -4\pi^2 f_1^2 v(f_1, f_2) e^{-2\pi f |x_3|} \\ \mathcal{G}_{1,2}(f_1, f_2; x_3) &= -4\pi^2 f_1 f_2 v(f_1, f_2) e^{-2\pi f |x_3|} \\ \mathcal{G}_{1,3}(f_1, f_2; x_3) &= -i4\pi^2 f_1 v(f_1, f_2) e^{-2\pi f |x_3|} \\ \mathcal{G}_{2,2}(f_1, f_2; x_3) &= -4\pi^2 f_2^2 v(f_1, f_2) e^{-2\pi f |x_3|} \\ \mathcal{G}_{2,3}(f_1, f_2; x_3) &= -i4\pi^2 f_2 v(f_1, f_2) e^{-2\pi f |x_3|} \\ \mathcal{G}_{3,3}(f_1, f_2; x_3) &= 4\pi^2 f^2 v(f_1, f_2) e^{-2\pi f |x_3|}. \end{aligned} \quad (40)$$

These relationships can be used to determine any gradient from any other gradient or from any derivative of the potential. For example, the gradient, Γ_{13} , at altitude, x_3 , is the inverse Fourier transform of $f \times 2 \times \pi \times f_1 \times \gamma(f_1, f_2) e^{-2\pi f |x_3|}$, where $\gamma(f_1, f_2) = -2\pi f v(f_1, f_2)$ is the Fourier transform of the vertical derivative of V (the gravitational acceleration) at ground level. In such transformations, due care must be exercised when calculating the higher frequencies of the gradients if the original data have noise and are limited in resolution due to finite data spacing.

Reference Field and Power Spectral Density

The first-order approximation of the Earth's gravity potential is the “normal potential,” which includes the centrifugal component due to Earth's rotation and whose defining property is that it is constant on a co-rotating ellipsoidal model for the Earth. It may be expressed by the spherical harmonic expansion,

$$U(r, \theta, \lambda) = \frac{GM}{r} \left(1 - \sum_{n=1}^{\infty} J_{2n} \left(\frac{a}{r} \right)^{2n} P_{2n}(\cos \theta) \right) + \frac{1}{2} \omega_e^2 r^2 \sin^2 \theta, \quad (41)$$

where a is the semimajor axis of the ellipsoid, ω_e is Earth's rotation rate, and the coefficients are given by

$$J_{2n} = (-1)^{n+1} \frac{3e^{2n}}{(2n+1)(2n+3)} \left(1 - n + 5n \frac{J_2}{e^2} \right), \quad (42)$$

where e is the first eccentricity of the ellipsoid, and J_2 is the dynamical form factor related to the difference in principal moments of inertia of the Earth, or also the polar flattening of the ellipsoid (Heiskanen and Moritz 1967; Hofmann-Wellenhof and Moritz 2005). The series (41) is usually truncated at $n = 5$ with entirely sufficient accuracy. For values of the defining parameters, GM , a , J_2 , ω_e , of the current and past reference fields, see chapter ► “Gravity Field of the Earth.”

The normal gravity potential, U , does not depend on longitude due to the rotational symmetry of the ellipsoid; and, in view of Eq. (14), only the local gravity gradients, $\Gamma_{1,1}$, $\Gamma_{1,3}$, $\Gamma_{2,2}$, and $\Gamma_{3,3}$, include a normal component. A standard approximation for the normal gradient $\Gamma_{3,3}^{(U)}$ is $\Gamma_{3,3}^{(U)} \approx 3086 \times 10^{-9} \text{ s}^{-2}$, based on just the first term in Eq. (41). The common unit of measure for gravity gradients is the Eötvös ($1 \text{ E} = 10^{-9} \text{ s}^{-2}$), in honor of the Hungarian geophysicist, Loránd Eötvös, who invented the torsion balance (section ► “Gravity, Gradiometry”).

The residual potential, actual minus normal potentials, also called the disturbing potential, then gives rise to gradient disturbances, which may in some instances attain an order of magnitude similar to the reference part, especially in very mountainous areas (e.g., Hein 1977).

Globally, the power spectral density (PSD) of the potential, defined on the sphere of radius, R , is given in terms of its Fourier-Legendre spectrum by (Jekeli 2017)

$$\Phi_n = \frac{1}{2n+1} \left(\frac{GM}{R} \right)^2 \sum_{m=-n}^n C_{n,m}^2. \quad (43)$$

Corresponding radial derivatives have PSDs scaled by fixed powers of the degree, meaning that they emphasize the higher degrees or shorter wavelengths of the field. Figure 3a shows the PSDs of the disturbing potential and its first two radial derivatives (relative to the normal field) according to the Earth Gravitational Model 2008 (EGM2008, Pavlis et al. 2012).

Also shown (Fig. 3b) is the cumulative contribution of the disturbing field and its radial derivatives up to a given degree, n , or resolution, where spatial resolution (half-wavelength) in kilometers is given by $\Delta s = 6371\pi/n$, 6371 km being the mean Earth radius. While about 99.3% of the disturbing

Gravity, Gradiometry, Fig. 3 (a) Power spectral densities of radial derivatives of the Earth's disturbing potential normalized by the respective total variance. (b) Cumulative relative power of each radial derivative as function of spatial resolution of the field

potential is defined by the field with wavelengths longer than 2000 km, the gravity disturbance (first radial derivative) comprises only about 41.4% up to these wavelengths, and the gradient disturbance barely has any (relative) power at wavelengths longer than 200 km. Here, it is noted that the cumulative contribution of the gradient disturbance is highly dependent on the local field and is only an illustrative example. As another example, Jordan (1978) provided a PSD model wherein 99.995% of the power of the gradient disturbance is due to the density variations in the upper 150 m of the crust, while this regime contributes 89% to the gravity disturbance and only 7% to the disturbing potential.

Measurement Error Analysis

All currently operational gravity gradiometers measure “gradients” by differencing, in one form or another, the inertial accelerations sensed by linear or angular accelerometers. In the limit of infinitesimal separation, the model with linear accelerometers can be used to derive the theoretical equation for gravity gradiometers, which also offers a general interpretation of measured gradients on a moving platform. We start

Gravity, Gradiometry, Fig. 4 The geometry for the lever-arm effect on the acceleration of m in the b -frame rotating with respect to the i -frame

with the lever-arm equation (Jekeli 2000) for the output of an accelerometer (Fig. 4),

$$\mathbf{a}^b = \mathbf{a}_0^b + (\mathbf{g}_0^b - \mathbf{g}^b) + \dot{\Omega}_{ib}^b \mathbf{x}^b + \Omega_{ib}^b \Omega_{ib}^b \mathbf{x}^b, \quad (44)$$

where $\mathbf{a}^b$ is the inertial acceleration of a test mass, m , in a frame (the b -frame) that rotates with respect to the inertial frame (i -frame) with angular rate given by the vector, $\boldsymbol{\omega}_{ib}^b = (\omega_1 \ \omega_2 \ \omega_3)^T$, expressed in terms of a cross product as

$$[\boldsymbol{\omega}_{ib}^b \times] = \Omega_{ib}^b = \begin{pmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{pmatrix}. \quad (45)$$

The acceleration of the b -frame in the i -frame is $\mathbf{a}_0^i$, and the location of the test mass (the lever-arm) in the b -frame is $\mathbf{x}^b$. The gravitational acceleration of the b -frame (in b -frame coordinates) is $\mathbf{g}_0^b$ and that of the test mass is $\mathbf{g}^b$. The last two terms of Eq. (44) represent, respectively, Coriolis and centrifugal accelerations due to the frame rotation.

The spatial derivative of Eq. (44), analogous to differencing the inertial accelerations of two test masses in the b -frame, yields

$$\frac{\partial \mathbf{a}^b}{\partial \mathbf{x}^b} = -\frac{\partial \mathbf{g}^b}{\partial \mathbf{x}^b} + \dot{\Omega}_{ib}^b + \Omega_{ib}^b \Omega_{ib}^b, \quad (46)$$

showing that the measured acceleration gradient is the combination of the gravitational gradient and angular accelerations. Thus, a gravity gradiometer must either be stabilized against rotations with respect to the inertial frame or some

Gravity, Gradiometry, Table 1 Roughly commensurate (per row) sensor errors in mobile gravity gradiometry. Emphasized entries represent typical calibrated error levels for high-accuracy components

Gradiometer white noise	Orientation error	Gyro bias	Gyro white noise
30 E/ $\sqrt{\text{Hz}}$	20°	0.5°/h	3°/h/ $\sqrt{\text{Hz}}$
10 E/ $\sqrt{\text{Hz}}$	6°	0.15°/h	1°/h/ $\sqrt{\text{Hz}}$
1 E/ $\sqrt{\text{Hz}}$	0.6°	0.015°/h	0.1°/h/ $\sqrt{\text{Hz}}$
0.1 E/ $\sqrt{\text{Hz}}$	0.06°	0.0015°/h	0.01°/h/ $\sqrt{\text{Hz}}$
0.01 E/ $\sqrt{\text{Hz}}$	0.006°	0.00015°/h	0.001°/h/ $\sqrt{\text{Hz}}$

other realizable frame, or these rotations must be measured independently with gyroscopes. An analysis of the required accuracy of these measurements (or, equivalently, of the stabilization) was conducted by Jekeli (2006) and is summarized in Table 1. Each row of this table corresponds approximately to commensurate sensor errors (gradiometer and gyroscope). For typical airborne gradiometer systems with noise levels in the range 1 – 10 E/ $\sqrt{\text{Hz}}$, conventional high-accuracy gyroscopes are sufficient to separate the gravitational gradients from the non-gravitational components. It is also evident that the sensitivity to position error (registration error) is not strong in view of the relatively small spatial gradient of the gravitational gradients, of the order of 1.45×10^{-3} E/m for the main field.

Due to the symmetry of the gravitational tensor, $\Gamma^b = (\partial \mathbf{g}^b / \partial \mathbf{x}^b)$, and the anti-symmetry of Ω_{ib}^b , the measurement of the full matrix, $(\partial \mathbf{a}_m^b / \partial \mathbf{x}^b)$, permits some simplifications, such as

$$\Gamma^b = -\frac{1}{2} \left(\frac{\partial \mathbf{a}^b}{\partial \mathbf{x}^b} + \left(\frac{\partial \mathbf{a}^b}{\partial \mathbf{x}^b} \right)^T \right) + \Omega_{ib}^b \Omega_{ib}^b. \quad (47)$$

The next section offers further details on the measurement of gravity gradients.

Gradiometry

Whereas the gravity meter, or any other accelerometer, senses the inertial reaction of a single test mass to an applied force, the (gravitational) gradiometer senses the difference of reactions from two test masses. In general terms, one may think of a gradiometer as the juxtaposition of two accelerometers and the sensed gradient as the ratio of the acceleration difference to the baseline length between them. As such the gradiometer measures only an approximation of the gradient at a point, which is adequate for sufficiently small baselines. Measuring the entire tensor of gradients (a “full-tensor gradiometer”) requires a minimum of 12 accelerometers as shown in Fig. 5, although, because some gradients share an accelerometer in this configuration, the errors between them may be

Gravity, Gradiometry, Fig. 5 Conceptual minimal configuration for a full-tensor gradiometer

correlated. Completely independent measurements of all nine tensor elements, therefore, require 18 accelerometers. On the other hand, taking advantage of the tensor symmetry and Laplace's field Eq. (8) brings the minimum to five accelerometer pairs.

Most gradiometers actually are designed to sense components of the differential curvature of the field (Eq. 12), and thus they rely on Laplace's equation to determine the individual diagonal components. Specifically, imagine that a gradiometer senses $\Gamma_{2,2} - \Gamma_{1,1}$ and $\Gamma_{1,2}$ in the instrument frame. Combining three such devices with mutually orthogonal orientation within the instrument system (Fig. 6) thus yields in addition to $\Gamma_{1,2}$, $\Gamma_{2,3}$, $\Gamma_{3,1}$ the components $\Gamma_{2,2} - \Gamma_{1,1}$, $\Gamma_{3,3} - \Gamma_{2,2}$, and $\Gamma_{1,1} - \Gamma_{3,3}$. The latter always sum to zero (except for measurement errors) and cannot by themselves separate the diagonal elements of the tensor. Nevertheless, it is common to refer to this as a full-tensor gradiometer (FTG), even though effectively only five of the nine tensor elements are sensed independently.

The first instrument specifically designed to measure the gravity gradient was the torsion balance, invented by the Hungarian geophysicist, Loránd Eötvös (1848–1919), at the end of the nineteenth century (One makes the distinction in geodesy between “gravitation” and “gravity,” where the latter refers to measurements on the Earth's surface and is the vector sum of acceleration due to mass attraction (gravitation) and the centrifugal acceleration associated with Earth's rotation). Prolific in many endeavors of exploration geophysics, one of his passionate goals was to design an instrument that could sense all gravitational gradients (he left the vertical-vertical gradient to others, since it would not be possible for his apparatus) (Szabó 1998).

Eötvös adapted the concept of Coulomb's torsion balance (designed to sense electrostatic forces) to measure gravitational

Gravity, Gradiometry, Fig. 6 Mutually orthogonal gradiometer sensors in the “umbrella configuration”

Gravity, Gradiometry, Fig. 7 Eötvös's original torsion balance (left, from Szabó 1998, reprinted with permission, Eötvös Loránd Geophysical Institute of Hungary) and the more modern version manufactured by the Eötvös Loránd Geophysical Institute of Hungary, Budapest in the 1950s (right, from Badekas 1967)

gradients. After several initial prototype instruments, including the curvature variometer, which was sensitive to the differential curvature components (Eq. 12), and the horizontal variometer, which measured the horizontal gradients (Γ_{13} , Γ_{23}), the final product combined these into one instrument, shown in Fig. 7. Two equal masses, m , are attached to the ends of a beam of length, 2ℓ , which is suspended by a platinum-iridium (or, tungsten) wire that may twist about the vertical axis in response to the curvature of the gravitational field. If both masses were at the same height ($h = 0$, in Fig. 7), the instrument would be the curvature variometer. With the vertical offset of one mass, the instrument is also sensitive to the horizontal gradients.

Assuming the beam has negligible mass, the torque on the beam is

$$\mathbf{L} = \mathbf{r}_A \times m\mathbf{g}_A + \mathbf{r}_B \times m\mathbf{g}_B, \quad (48)$$

where $\mathbf{r}_A = (-x, -y, 0)$ and $\mathbf{r}_B = (x, y, h)$ are the position vectors of the masses in a north-east-down coordinate system with origin at the instrument center, and $\mathbf{g}_A$, $\mathbf{g}_B$ are the gravity

vectors at these points. The torque component about the vertical is

$$L_3 = mx(g_2(x, y, h) - g_2(-x, -y, 0)) + my(g_1(-x, -y, 0) - g_1(x, y, h)). \quad (49)$$

To first-order approximation, the gravity components are

$$g_1 = \Gamma_{1,1}x + \Gamma_{1,2}y + \Gamma_{1,3}z, \quad (50)$$

$$g_2 = \Gamma_{2,1}x + \Gamma_{2,2}y + \Gamma_{2,3}z, \quad (51)$$

which yields

$$L_3 = 2m(x^2 - y^2)\Gamma_{1,2} + 2mxy(\Gamma_{2,2} - \Gamma_{1,1}) + mh(x\Gamma_{2,3} - y\Gamma_{1,3}). \quad (52)$$

Here, the $\Gamma_{j,k}$ are gravity gradients as opposed to the gravitational gradients of the previous sections.

We may introduce the azimuth, α , of the instrument with respect to north, such that $x = \ell \cos \alpha$ and $y = \ell \sin \alpha$. Then using the angular form of Hooke's law, $L_3 = -\tau(\theta_\alpha - \theta_0)$, Eq. (52) becomes

$$-\tau(\theta_\alpha - \theta_0) = m\ell^2((\Gamma_{2,2} - \Gamma_{1,1}) \sin 2\alpha + 2\Gamma_{1,2} \cos 2\alpha) + m\ell h(\Gamma_{2,3} \cos \alpha - \Gamma_{1,3} \sin \alpha), \quad (53)$$

where τ is the torsion coefficient of the wire; θ_0 is the torsion-free, zero-direction of the beam; and θ_α is the angle of the beam relative to the zero-direction when the instrument (casing) is placed at azimuth, α . Measurements at several azimuths are required to determine all unknown quantities: $\theta_0, \Gamma_{2,2} - \Gamma_{1,1}, \Gamma_{1,2}, \Gamma_{1,3}, \Gamma_{2,3}$.

Eötvös designed several other versions, such as the double torsion balance (two opposing beams) that he used to study the equivalence of inertial and gravitational mass (which Einstein postulated as intrinsically true for his general theory of relativity; see section ► “Magnetic Gradiometry”). Though quite laborious and extremely sensitive to nearby masses in the field, the torsion balance (several versions built by various manufacturers) was widely used for geophysical prospecting of oil and gas in the early twentieth century both in Europe and in the USA. Ultimately, it gave way to the more efficient and equally accurate land gravity meter (Nettleton 1976; Chapin 1998).

Gravity gradiometry did not regain significant attention until the dawn of the space age since only gradiometers on planetary probes can make in situ measurements of the gravitational field. Early developments of moving-base gradiometers mimicked the torsional sensing apparatus, similar, in principle, to Eötvös's horizontal variometer, but in a smaller package (thus sensing only $\Gamma_{2,2} - \Gamma_{1,1}$ and $\Gamma_{1,2}$ in a local frame; Eq. (53) with $h = 0$). In addition, by rotating the device about the axis perpendicular to the mass baseline, the sensed gradients are modulated by twice the rotation rate due to the symmetry of the mass-baseline configuration. In this way some of the errors (such as accelerometer scale mismatches and misalignments) that modulate at once the rotation rate, Ω , can be separated in the frequency domain from the gradient signal that is modulated at twice this rate. That is, demodulation of the output signal at frequency, 2Ω , effectively filters these errors.

One of the earliest modern gradiometers was developed by Hughes Aircraft Research Laboratories for a lunar orbiter mission, the Hughes Rotating Gravity Gradiometer (RGG) (Forward 1981). Figure 8 shows a schematic of the device that senses the relative torques on the two arms that are coupled to the base by torsion pivots. Two dumbbells are required to

Gravity, Gradiometry,

Fig. 8 Concept (from Heller 1977) and breadboard model (from Forward 1981) of the Hughes Aircraft Rotating Gravity Gradiometer

distinguish the gravitational gradients from torques on the case in a dynamic environment. Furthermore, the rotation rate of the device is designed to be half its mechanical resonant frequency so as to amplify sensed gradients. A demonstration model of the RGG (which was never put into operation) had a diameter of 14 cm and an accuracy of 1 E for a 10 s integration time (Forward 1981).

The Charles Stark Draper Laboratory of Cambridge, Massachusetts, using its leading expertise in gyroscope technology, also devised several gradiometer concepts for moving-base applications. The “floated gradiometer,” pictured in Fig. 9a, was derived from the floated gyroscope whose buoyant/viscous/magnetic support system is virtually insensitive to high levels of acceleration and vibration. In this case, the device, like Eötvös’s torsion balance, had two anomalous masses at different heights (skewed mass configuration). If, for example, $\alpha = -90^\circ$ is substituted in Eq. (53) (maintaining the north-east-down coordinate system and indicating that the first axis of the device points west, toward $-x_2$), then the measurement is the applied restoring moment, M , in response to a deflection due to the gradients,

$$M = \tau(\theta_x - \theta_0) = 2m\ell^2\Gamma_{1,2} - m\ell h\Gamma_{1,3}, \quad (54)$$

where ℓ is the radius of the device.

On a stabilized platform with axes constrained to the local north-east-down directions, a cluster of three such devices (Fig. 9b) yields measured moments,

$$\begin{aligned} M_1 &= 2m\ell^2\Gamma_{1,2} - m\ell h\Gamma_{1,3} \\ M_2 &= 2m\ell^2\Gamma_{1,2} + m\ell h\Gamma_{1,3} \\ M_3 &= -2m\ell^2\Gamma_{1,2} + m\ell h\Gamma_{2,3} \end{aligned} \quad (55)$$

which can be combined to yield the horizontal gradients, $\Gamma_{1,3}$ and $\Gamma_{2,3}$. Derived from the differences of corresponding torques (as shown), these measured gradients are insensitive

to angular accelerations about the vertical axis, the direction about which a north stabilized platform is least accurate. Later designs used electrostatically suspended spheres, with anomalous masses, that in an appropriate triad configuration would constitute a full-tensor gradiometer (with Laplace’s constraint) and be less susceptible to platform jitter effects (Wells 1984). Like the Hughes Aircraft instruments, the Draper Lab gradiometers did not reach the production stage but did demonstrate very good performance in the laboratory.

Another concept that utilized device rotation to separate the gradient signal from noise sources in the frequency domain was the gravity gradiometer instrument (GGI) of Bell Aerospace. The instrument consisted of pairs of accelerometers mounted on a rotating disk as shown in Fig. 10 (left). The input axes are perpendicular to the radius of the disk, and, thus, in analogy to the Hughes Aircraft RGG, their measurements may be thought of as proportional to torques about the spin axis. Substituting $\alpha = \Omega t$ and $\alpha = \Omega t + \pi/2$ for the respective pairs of accelerometers and $M = mr(a_1 + a_2)$ and $M = mr(a_3 + a_4)$ for the respective torques into Eq. (53) (with $h = 0$), the measurement equation, therefore, is given by

$$\begin{aligned} a_1(t) + a_2(t) - (a_3(t) + a_4(t)) \\ = 2r(\Gamma_{2,2} - \Gamma_{1,1}) \sin 2\Omega t + 4r\Gamma_{1,2} \cos 2\Omega t, \end{aligned} \quad (56)$$

where Ω is the spin rate of the disk and t is time. The factor of 2 on the right side comes from the dual pairs of accelerometers. This instrument has been used for military and commercial applications, and today’s version (acquired by Lockheed Martin, Fig. 10, right) has four pairs of accelerometers per disk, thus, in essence, further doubling the signal amplitude in the output (Schweitzer et al. 2000). However, three GGIs are still needed (e.g., in the configuration of Fig. 6) to obtain all elements of the gradient tensor.

The Bell Aerospace (Lockheed Martin) gradiometer is currently operated for various geophysical and geodetic

right, the full-tensor 3 GGI system of Bell Geospace (Murphy 2004; reproduced with permission, Bell Geospace). Both systems are shown on inertially stabilized platforms

applications by CGG (Compagnie Générale de Géophysique, using improved versions of the erstwhile BHP Falcon single-disk system, Fig. 11) and by Bell Geospace (full-tensor gradiometer, with the original four-accelerometer disks). These systems used primarily in the airborne mode for high efficiency have also been deployed on ocean vessels and ground vehicles.

Satellite in situ gravitational field measurements are limited fundamentally to gradiometry. Aside from small atmospheric drag forces and solar radiation (and Earth albedo) pressure, an Earth-orbiting satellite is in free fall. Accelerometers (at the center of mass) on a satellite sense only the non-gravitational forces, but a gradiometer, as on any moving

platform, senses the gravitational gradient (Eq. 46). Satellite gradiometry has a long, interesting, and ultimately successful history. Besides the Hughes RGG (which did not fly on a satellite), a major effort was undertaken by NASA to put a superconducting gravity gradiometer (SGG) into low Earth orbit in the 1980s. The SGG was developed by the University of Maryland (Moody et al. 1986; Paik et al. 1988) as an outgrowth of the technology for highly sensitive gravity wave detectors. Based on accelerometers that use the magnetic flux exclusion principle of superconducting bodies, the SGG was designed primarily to sense the in-line gradients. Referring to Fig. 12 (left), as the gap between the superconducting proof mass and the sensing coil changes due to

Gravity, Gradiometry,

Fig. 13 GOCE core gradiometer assembly (left) and total instrument (right)

acceleration, the magnetic flux is forced out of the sensing coil and into the input coil of a superconducting quantum interference device (SQUID), which is able to sense extremely small changes in the flux. The system was not flown on a satellite but did contribute to physics experiments involving the search for non-Newtonian gravitational effects (see section ► “Magnetic Gradiometry in Archaeo-geophysics”).

In March 2009, the first satellite-borne gravity gradiometer was launched by the European Space Agency (ESA) into low Earth orbit (altitude = 255 km) for a mission to map the Earth’s gravitational field globally to a resolution of 100 km, or better (Drinkwater et al. 2003). The *Gravity field and steady-state Ocean Circulation Explorer* (GOCE) gradiometer is a true full-tensor device (Fig. 13), based on three pairs of three-axis accelerometers, separated pair-wise by 0.5 m, thus in principle measuring all nine elements of the tensor, $\partial^2 a^b / \partial x^b$ (Eq. 46). Similar to airborne gravity gradiometry, the dynamical orbit of the satellite need not be determined with exquisite accuracy, and tracking was performed by the (nevertheless very precise) Global Positioning System (GPS). More

important is the attitude stabilization (see Eq. 47), and this was controlled by an active ion-propulsion drag compensation system, as well as onboard star trackers and magnetic torquing (Sechi et al. 2006), yielding a drag-free stabilized gradiometer platform. The originally planned 20-month mission lasted for about 55 months until in November 2013 the orbital decay could no longer be controlled resulting in the satellite’s demise.

Each accelerometer of the GOCE gradiometer has one weakly prelaunch calibrated axis, due to the earthly 1-g laboratory environment. As a consequence, the in-line components, $\partial a_1 / \partial x_1$, $\partial a_2 / \partial x_2$, $\partial a_3 / \partial x_3$, and the cross components, $\partial a_1 / \partial x_3$, $\partial a_3 / \partial x_1$, are the most accurate. The latter allow an accurate determination of the angular velocity, ω_2 , about the normal to the orbital plane, which is greatest in magnitude (Earth-pointing stabilization), since from Eq. (46) and the symmetry of the gravity gradient tensor, we have

$$\frac{\partial a_1}{\partial x_3} - \frac{\partial a_3}{\partial x_1} = 2\dot{\omega}_2. \quad (57)$$

As a consequence and since ω_1 and ω_3 are comparatively small, the most accurate gravity gradients obtained by the GOCE gradiometer are the in-line gradients and the cross gradient, $\Gamma_{1,3}$ (Rummel et al. 2011).

Other types of gradiometers may be found discussed in the literature and are at various stages in their development. For example, a cryogenic gradiometer based on the same principle as the Hughes Aircraft RGG is being constructed and tested by the Canadian company, Gedex (Tryggvason et al. 2004). Stanford University has investigated a gradiometer using dual cold-atom interferometer accelerometers (McGuirk et al. 2002). And, MEMS (microelectromechanical systems) technology is being applied to the manufacture of miniature gradiometers (Flokstra et al. 2009). The reader is referred also to the review by Difrancesco (2007).

Designing and using a gravity gradiometer system requires consideration of several significant sources of error. Gradiometers on a moving platform must detect a very small differential gravitational signal buried in a large-amplitude acceleration environment. An accuracy of 1 E over an accelerometer baseline of 0.1 m implies better than $7 \times 10^{-11} \text{ m/s}^2$ accuracy in the sensed accelerations, a resolving power that is challenging for most accelerometers. Rotation of the gradient sensor has been a key development to separate signal from noise in the frequency domain. Cryogenics is another solution, as is the dynamically quiet environment of a space vehicle.

Essential error sources for accelerometer-based gradiometers include the scale factor and bias stability of the accelerometers, as well as the degree to which their scale factors are matched and their sensitive axes are aligned. These all determine how well the common linear acceleration is rejected in the difference that ideally leaves only the gravitational gradient (with proper stabilization). Often, specialized electronic or mechanical devices or procedures (rotation and induced shaking) are used to eliminate or calibrate these erroneous effects. A particularly important calibration is the self-gradient of the vehicle that carries the gradiometer. Since the platform is stabilized (e.g., in the local level frame), the rotation of the vehicle about the platform creates a varying gradient field due to the changing attitude of the vehicle masses. This field must be calibrated, often using elaborate procedures that place the vehicle in varying attitudes while the gravitational field is constant (i.e., the vehicle is stationary) – see (Jekeli 1988b).

In summary, the development of instruments that measure gravitational gradients spans over 100 years; and, despite a variety of system advancements, mostly to make gradiometry mobile, many modern sensor concepts have strong analogies to the original Eötvös curvature variometer – they measure differential curvature parameters. In-line differential accelerometers are the only systems that have been or are in operation for scientific purposes, both on Earth and in orbit; but other technologies are also in development for future systems. The 1 E

accuracy of the Eötvös torsion balance rivals or still bests the terrestrial mobile systems of today, but the latter have improved the integration time vastly from many hours to tens of seconds, or better. In principle, gradiometry relies primarily on the technology of inertial sensors, and the theoretical limit in measurement precision in many cases has not yet been reached at the operational level. It is clear that gravity gradiometry is the holy grail of precision gravimetry on moving platforms – the future will see many more ideas and prototype sensors added to the existing repertoire of instruments.

Applications

One of the more interesting applications of the torsion balance was Eötvös's experimental validation of the equivalence of inertial and gravitational mass, assumed by Einstein in his theory of general relativity. Inertial mass is the proportionality factor between velocity and linear momentum (or, between acceleration and *applied* force), while gravitational mass is the proportionality factor between gravitational acceleration and gravitational force. Conceptually, the acceleration caused by the gravitational attraction of a mass body need not be indistinguishable from the acceleration caused by a force, such as propulsion, friction, or similar physical action. Yet the assumption of their equivalence led Einstein to his very successful theory.

Eötvös experimented already in the 1890s with the question of dependence of gravitational attraction on the composition of mass (continuing with Galileo's experiments that showed no such dependence). The idea of his experiment is illustrated in Fig. 14 showing that different types of test

Gravity, Gradiometry, Fig. 14 Eötvös's experiment to determine if different types of mass experience different gravitational accelerations (g versus g') that could be measured as a deflection, θ , with respect to the constant centrifugal acceleration, a

masses on the beam of the torsion balance might yield different gravitational accelerations that in combination with the unchanging centrifugal acceleration due to Earth's rotation would yield a measurable deflection. Eötvös et al. (1922) found no deviation at the 5 part-per-billion level. If indeed, such a deflection is detected, it could also be interpreted as evidence of a non-constant gravitational constant or an additional non-Newtonian force (Fischbach et al. 1986; Fischbach and Talmadge 1992).

Another experimental test of Newton's law of gravitation involving gravitational gradients considers the sum of in-line gradients, which for a Newtonian field must sum to zero (Fig. 15) in a vacuum (Laplace's Eq. 8). Moody and Paik (1993) used a swinging pendulum in the laboratory to induce modulated in-line gradients that were measured with their superconducting gradiometer (section ► "Gravity, Gradiometry"). The sum of the measured gradients was zero with a statistical variation ($\sigma = 3 \times 10^{-4}$ E) that placed further limits on any local departure from Newton's law of gravitation.

The principal utility of the torsion balance and later the gravity gradiometer was and is in geophysical exploration. The Eötvös torsion balance (and its successors) played a significant part, with over a hundred in operation worldwide, in the exploration for oil and gas reservoirs in the early twentieth century, 1918–1940. The achievable accuracy was as good as 1–3 E, but the measurements were arduous, requiring up to 6 h per station. Thus, the torsion balance quickly lost ground when the more portable and robust, as well as sufficiently accurate spring-type gravimeters were developed in the 1930s and 1940s.

Gravity gradiometry in modern times is conducted almost exclusively with mobile systems, in order to take advantage of the increased resolution capability and avoiding the difficulty

of separating the kinematic and inertial accelerations, required in mobile gravimetry systems (Jekeli 2000). Submarine gradiometers are used to compensate inertial navigation systems for the effects of gravity and shipborne gradiometers have been used for marine gravity surveys. A significant investment has been made by a number of commercial exploration companies to use airborne gradiometers to map the gravitational field at high resolution in search for minerals, such as diamonds found in kimberlite pipes (Liu et al. 2001).

The first satellite-borne gradiometer mission to map the Earth's global gravitational field, GOCE, has yielded a number of high-resolution (100 km) global models derived solely from satellites and expressed as series of spherical harmonics. Since the gravitational gradients emphasize the shorter spatial wavelengths, most of these global models are obtained by combining the GOCE data with other satellite-tracking data, e.g., from GPS (Pail et al. 2011), or often the data from other satellite missions, specifically GRACE (Tapley et al. 2004), as well as previous long-wavelength models derived from ground-based tracking of a multitude of satellites. Furthermore, terrestrial gravity data serve to complement the satellite data for so-called combination models (e.g., Fecher et al. 2017). On the other hand, after more than 3 years of GOCE data, a model based exclusively on these data was also developed (Brockmann et al. 2014). Besides the global models, the GOCE mission has opened a new chapter on regional gravity modeling (e.g., Eicker et al. 2014; Lieb et al. 2015; Wu et al. 2017), as well as subsurface geophysics (e.g., Ebbing et al. 2013; Bouman et al. 2016; Eshagh and Pitoňák 2019). These detailed models of the global and regional field will continue to advance the Earth sciences in many fields, from oceanography to regional tectonics and the dynamics of the upper mantle and crust, and to polar ice sheets and glaciology.

Gravity, Gradiometry,

Fig. 15 Experimental setup to test Laplace's equation by measuring the sum of in-line gradients modulated by the changing gravitational field induced by a swinging pendulum (from Paik 2004; reprinted with permission of author)

Summary

Gravity gradiometry is a highly specialized approach to mapping the finer details of a gravity field. Although gradient sensors have existed for well over a century, the most efficient applications have come more recently from their deployment on moving-base systems, such as on ships, but more prominently on aircraft and space vehicles. From a theoretical viewpoint, measuring the gradients in these modes is more advantageous than measuring the field using conventional gravity meters since they are insensitive, in principle, to the linear accelerations of the vehicle, and sensing gradients implies detecting the shorter-wavelength features of the field. Despite these benefits, in practice, developing sensors of functional precision needed to discern these relatively small quantities requires exquisite isolation of vibrations and scale factor calibration. For this reason, to date there are but a few systems in operation.

Great Earthquakes

Roger M. W. Musson
British Geological Survey, Edinburgh, UK
School of Geosciences, University of Edinburgh,
Edinburgh, UK

Definition

Any earthquake with magnitude over 8 Mw. Alternatively, any earthquake famous for one reason or another

Introduction

Under the technical definition, one can find some very obscure “great” earthquakes – a magnitude 8 earthquake in the Southern Ocean is likely to go wholly unremarked by the world’s media. Also, given the inherent imprecision in magnitude scales, it is possible for an earthquake with a magnitude of 8.0 to be successively promoted to and demoted from the canon of greatness with each successive revision.

If one took a sample of educated laymen and asked them to name any earthquakes they could think of, one could be sure to get a few of the most recent high-profile calamities; further back the results might vary from country to country. In the central USA, probably many are aware of the 1811 New Madrid earthquakes; in central Europe, the name of the 1356 Basel earthquake might come up; and so on. But probably not many could name correctly the largest earthquake ever known, the 1960 Valdivia, Chile, earthquake, which reached 9.6 Mw in magnitude, a value many seismologists suspect to be a physical upper limit of earthquake size. This devastating earthquake also produced a huge tsunami, which, on the Chilean coast, pitched boats up to 3 km inland (see Box-Out: The Ten Largest Earthquakes).

The title “largest earthquake ever” gives the 1960 Valdivia event an indisputable claim to greatness by any reckoning. Other earthquakes are famous for a variety of reasons: their place in history, the lessons learned from them, their significance in the development of seismology, or their sheer excessive destructiveness. The earthquakes of 1356 and 1811 mentioned above are both important for the same two reasons – they demonstrate that significant earthquakes can still

occur well away from plate boundaries and also that the historical record can reveal potential threats in places not much remarked for seismicity today.

The 1556 Shaanxi earthquake bears the record for being the most deadly earthquake on record, with about 830,000 dead. The figure of one million dead in one earthquake has not yet been reached (contrary to some sources, the 20 May 1202 earthquake in the Levant did not kill this many; Ambraseys and Melville 1988), but, with several current megacities dangerously exposed, it is feared that it is only a matter of time (see Box-Out: The Ten Deadliest Earthquakes).

There are probably four earthquakes that stand out as the most unquestionably great earthquakes of history. First was the 1755 Lisbon earthquake. Not only was this (with its accompanying tsunami) one of the most deadly and devastating earthquakes in European history (not forgetting its impact on North Africa), it sent shock waves throughout the whole of Western culture. Second, the 1906 San Francisco earthquake so ingrained itself into history that the very name of San Francisco conjures earthquakes to mind, to which must be added the important role this event played in the development of seismological theory. Third, the 2004 Sumatra earthquake, staggering in its immensity, changed both the popular and professional understanding of earthquakes. Lastly and more recently still, the 2011 Tohoku earthquake ended up being responsible for the worst nuclear accident since Chernobyl.

1 November 1755: The Advance of Rationalism

Of all great earthquakes, the one with the most lasting impact is certainly the Lisbon earthquake of 1755. Not only did it destroy what was then one of the most important cities in the world, the capital of the Portuguese empire; it shook up the very development of Western philosophy. Furthermore, it continues to be controversial among seismologists to this very day.

The first of November is the Feast of All Souls, one of the most solemn occasions in the calendar of the Catholic Church. It was on the morning of this day that a massive earthquake struck somewhere off the coast of Portugal. Damage occurred over a wide area across Portugal and western Spain; significant damage occurred even in Morocco. The shaking was perceptible throughout the Iberian Peninsula and into France. Even beyond France, long-period waves caused the agitation of water in ponds and lakes at great distances – as far away as Scotland (Loch Ness was disturbed) and Scandinavia.

The worst damage, however, occurred in Lisbon. The churches, many of which collapsed, were packed with worshippers when the quake struck, and casualties were heavy. The sea then mysteriously withdrew, leaving fishes floundering in the mud. Many ventured out from curiosity or to collect

some of the fish. Shortly afterward the tsunami roared in and surged up into the semi-ruined city, collapsing many buildings that had already been damaged by the earthquake.

All Europe was shocked, and not just by the scale of the destruction. It was axiomatic in Christian thinking that all prodigious events such as earthquakes were of divine origin. The milder ones were sent as a warning of God's displeasure; the more severe ones were a punishment to send mankind back on the path of righteousness. Furthermore, this was true whether or not it was appreciated that such events had natural causes, as many printed works of the previous century explicitly argued: God works through, and controls, the natural world. Whether or not earthquakes were due to natural causes (the dominant explanation at the time was the Aristotelian view that earthquakes were due to subterranean winds), the timing and location were divinely ordained (Walsham 1999).

But the injustice of the destruction of Lisbon strained this train of thought to breaking point. Not only did the earthquake occur on one of the holiest days of the Christian year – the godly citizens who were marking the occasion by attending mass were killed, whereas sinners who chose to spend the morning in playhouses or brothels by and large escaped. If this was God's judgment, it was a very strange one. The earthquake was seized upon by Voltaire as a means of attacking the optimistic school of philosophy characterized by Leibniz (Kendrick 1956). In Lisbon, a decree was issued that anyone found preaching that the earthquake was sent by God should be put to death.

For modern study of the 1755 earthquake, there are several sorts of information that can be used to try and understand which fault produced it. Firstly, there is the distribution of earthquake effects; for most historical earthquakes, analysis of the distribution of intensity is the predominant means of location, though this is markedly less easy for offshore events. Secondly, for tsunamigenic earthquakes like 1755, the time and run-up of the tsunami at different locations can be inverted to estimate the parameters of the engendering fault rupture. Thirdly, some use can be made of information from aftershocks. Since these are generally much smaller than the main event, they are usually felt only at short distances. Lastly, in the case of a major earthquake, there should be some geological trace of the structure that produced it.

In terms of available geological structures, there are two main candidates, and a possible third. The first, and most obvious, is the Gorringe Bank, a segment of the offshore plate boundary between Europe and Africa. This was identified as the source of the 1755 earthquake by Johnston (1996); it was also the location of a large earthquake in 1969, and the intensity distribution of the 1969 event resembled to some extent a scaled-down version of the pattern observed from the 1755 event (Levret 1991).

The second candidate is a more recent discovery – a fault off the coast of Portugal trending NNE-SSW showing signs of

recent activity (Baptista et al. 1998). This was named the Marquês de Pombal Thrust in honor of the man who oversaw the reconstruction of Lisbon. This fault provides a good fit to analyses of the tsunami arrivals on the Portuguese coast (Baptista et al. 2003). However, it doesn't seem very likely that an earthquake on this fault would have caused damage in Morocco.

The third is a controversial suggestion by Gutscher et al. (2002) and Gutscher (2004) that the causative feature was a N-S aligned subduction zone in the Gulf of Cadiz, dipping eastward under Gibraltar. Apart from the fact that the very existence of such a feature is disputed, if this was the source, it is hard to understand why Lisbon was destroyed in place of Cadiz. The earthquake is well described in Gibraltar itself, and damage was insignificant.

There are still more problems though. Given that the magnitude of this great earthquake must have been around 8.7 (Johnston 1996), none of the faults described seem long enough to host such a great earthquake. Recent suggestions to account for this propose multiple near-simultaneous earthquakes: Baptista et al. (2003) and Baptista and Miranda (2005) propose a composite source involving the Marquês de Pombal Thrust and a fault segment on the southern flank of the Guadalquivir Bank, while Vilanova et al. (2003) have the second earthquake on a fault in the Lower Tagus Valley, close to Lisbon. The issue is still unresolved and controversial; the source of this great earthquake is still an enigma.

18 April 1906: The Archetype of Earthquakes

The San Francisco earthquake of 18 April 1906 is of all earthquakes, probably the most iconic in popular culture, the one earthquake that practically any layman can mention. As Davison (1927) remarked, "if the Californian earthquake were the only shock known to mankind, the attention paid to it could hardly have been more exclusive." Not only was it a major disaster in a romantic locale, it even had a celebrity cast – Caruso being in the city at the time. Thanks to the telegraph, the news spread quickly around the world, much faster than had been the case in 1755.

As with the Lisbon earthquake, fire was a contributor to the damage; but this time, it was the major contributor. Earthquakes are great fire starters, upsetting stoves and breaking gas pipes. But they also hinder firefighting efforts. As the fire gripped the city, much of which consisted of wooden buildings, it was found that the water supply system was also damaged by the quake. Unable to use hosepipes, the city authorities resorted to trying to control the fire with a system of firebreaks. Unfortunately, this was carried out somewhat ineptly. The black powder that was used often simply set fire

to the building being blasted; and where it didn't, it blew houses into clouds of matchwood that easily ignited – the firebreaks being often created too close to the advancing flames. Furthermore, no attempt was made to check what the buildings marked for demolition actually contained. One such building, belonging to the Viavi pharmaceuticals company, contained a huge store of spirit alcohol. The resulting fireball so exacerbated the fire that probably another 50 blocks in the northern part of the city were destroyed as a result (Fradkin 2006).

The final death toll is a matter of dispute; initial figures of around 700 are clearly underestimates, partly for propaganda purposes (reporters were encouraged to call it the Great San Francisco Fire and play down mention of the earthquake). Current estimates are about 3000 dead (Stover and Coffman 1993).

From a seismological point of view, the 1906 earthquake is rather more straightforward than the 1755 event. The fault it occurred on is not just known; it is perhaps the most famous fault in the world: the San Andreas, forming the plate boundary between the North American and Pacific plates. This is a right-lateral strike-slip fault; the fault rupture extended probably around 430 km including the offshore extension, with slip of over 6 m in places (Lawson 1908–1910; Segall and Liskowski 1990; Stover and Coffman 1993). Since strike-slip faults are limited in width to the thickness of the crust, this gives a magnitude of only around 7.8 Mw. The felt area was much less than that of the Lisbon earthquake, covering only California and extending partially into Nevada and Oregon (attenuation of seismic shaking is higher in California than in Iberia).

The dislocation of fence posts across the fault trace made it very obvious that the earthquake was due to fault displacement. It was studying the 1906 rupture that led Reid (1910) to develop the theory of elastic rebound, which still underpins basic seismological theory today – that a fault gradually deforms due to the buildup of crustal stresses, until a locking asperity breaks, releasing energy as the fault violently snaps. The connection between earthquakes and faulting was well-known at the time; Hoernes (1878) held that the majority of earthquakes were tectonic in origin, due to displacement along fractures related to mountain building. As early as 1855, Lyell identified repeated earthquake-related faulting in New Zealand (Lyell 1856), but it is not clear that he understood that the fault produces the earthquake and not vice versa. The earliest statement that dislocation on a fault actually causes earthquake shaking seems to be Mallet (1851), but he was ahead of his time.

However, Reid's fundamental understanding began a new era in seismology, opening the door to the interpretation of seismograms in terms of fault mechanics (Wald et al. 1993; Agnew 2002).

26 December 2004: Cataclysm

Although most of the world's subduction zones are around the Pacific, there are two in the Indian Ocean: on the Makran coast of Iran and along the south coast of Sumatra (extending to Burma in the north and bending round to Java in the east). While the historical seismicity of Sumatra (including a major event in 1833) was by no means unknown (Newcomb and McCann 1987), it was not generally considered high on the list of potential localities for catastrophe before the earthquake of Boxing Day 2004. The epicenter was off the Sumatran coast at the northern end of the island, near Banda Aceh, and the rupture propagated almost entirely northward, for a staggering distance of 1600 km (Nalbant et al. 2005), reaching up to the Andaman Islands. The northern part of the rupture zone, where the plate boundary is extremely oblique to the direction of convergence, was almost north-south in orientation. The resulting tsunami, instead of heading off into the southern Indian Ocean as occurred in 1833, headed due east and west, hitting crowded tourist beaches in Thailand about 15 minutes later (shortly after 8 a.m. local time) and India and Sri Lanka two hours after that.

The effect was literally a cataclysm (Gr: down washing), as the waves swept inland up to about the 30 m mark in some places, causing immense destruction. About 230,000 lost their lives, of which 167,000 were in Indonesia. It tends to be the case that most high-fatality earthquakes kill local people in substandard housing; this event was exceptional in killing large numbers of foreign tourists, which accounts in part for the great impact of the event on public consciousness in the West. (For a while afterward, journalists would enquire of seismologists “will there be a tsunami?” even in cases for earthquakes in central Russia.)

The result was a sudden impetus toward installing tsunami warning systems in different parts of the world, though perhaps not always with the understanding that technical solutions are of limited use without the practical means to evacuate people at risk in a timely fashion.

Given that no earthquake anything like as large had occurred anywhere in the world since the 1960s, in the following days, the analysis of the earthquake tested the methods of modern seismology in new ways. The shock waves circled the globe, being distinctly recognizable even on the third pass, and even altered the rotation of the planet itself, the length of day dropping by up to $-5 \mu\text{s}$ (Bizouard 2005). The pole itself shifted by up to 2 mas (milliarcseconds) toward 90° E (Bizouard 2005; 1 mas equals an equatorial shift at the Earth's surface of 3.1 cm). The difficulty for analysts was caused by the excessive duration of the rupture; the unidirectional propagation of the rupture took about 10 minutes to reach its terminus. This complicated the seismic records as waves propagating from different parts of the rupture at

different times overwrote each other. The immediate impact was underestimation of the earthquake magnitude – immediate press releases giving values of 8.5 or 8.7. Initial attempts to model the slip distribution could only manage the southernmost part of the rupture (Ji 2004). The first complete slip models were made by Ammon et al. (2005) from a combination of body waves, intermediate-period waves and long-period waves, and Vigny et al. (2005) using an inversion of GPS data (the two models disagree extensively). The final magnitude assessment is 9.2 Mw.

Previously, it had been thought that such a large earthquake was impossible on this part of the Sunda thrust system, on tectonic grounds, and due to parts of the system having already broken in previous large earthquakes. The fact that the 2004 earthquake ruptured through segments that had already recently ruptured has caused seismologists to reassess the risk of great thrust earthquakes in other areas (e.g., Suárez and Albini 2009).

It was speculated at the time that the movement due to the earthquake would increase the stress on the Great Sumatran Fault, a strike-slip fault running the length of the island, and bring this close to failure (Nalbant et al. 2005). As of the time of writing, the expected event on this fault has not yet occurred. Instead, a remarkable cascade of events occurred on segments of the thrust zone south of the 2004 rupture, including further great earthquakes on 25 March 2005 and 12 September 2007 with magnitudes ≥ 8.5 Mw. Current estimates (e.g., Megawati and Pan 2009) are that there is still potential slip in this part of the system to make further great earthquakes on the coast of Sumatra a continuing threat.

11 March 2011: Prepared or Not Prepared?

Just over 6 years after the Great Sumatra earthquake, another event with magnitude over 9 occurred, this time off the east coast of Japan. The earthquake occurred during the working day (14:46 JST), with an epicenter offshore from Tohoku region and a rupture extending some 400 km, spreading bilaterally NNE and SSW of the epicenter, unlike the mostly unidirectional rupturing in 2004. Inevitably, this great offshore subduction earthquake (dubbed by some a “mega-thrust”) produced a major tsunami, and it is the tsunami that had the greatest impact. The death toll from the earthquake was a few hundreds, which for a magnitude 9 earthquake striking a heavily populated country has to be considered a remarkable achievement for Japanese earthquake engineering. But the tsunami killed about 20,000. What went wrong?

One factor was that some Japanese remembered previous tsunamis that had originated on the American side of the Pacific and which were therefore much attenuated by the time they reached Japan. This fostered the idea that tsunamis

were not especially dangerous. Footage from video cameras showed people idling on the harbor side while klaxons were still sounding the alert. There is even footage of one Japanese man laboriously lugging a heavy television set up a hill while the approaching tsunami is already visible behind him. The video record of this tsunami is extensive and often astonishing. It includes video made from a dashboard camera in a car that was picked up and tossed around by the tsunami. Amazingly, both driver and camera survived the experience.

More serious was the fact that Japanese authorities had severely underestimated the hazard. Before 2011, researchers had considered the subduction system east of Japan to be well-understood; that the plate interface regularly broke in a characteristic fashion, in which earthquakes of 7.0–7.5 Mw would rupture a single segment, and that there was therefore no risk of several segments failing together in a single devastating event (Hino 2015). Thus the areas marked out as safe refuges in the event of a tsunami were anything but safe. This was despite evidence that earthquakes in the distant past had caused great tsunamis, notably the Jogan earthquake of 869 (Abe et al. 1990; Sawai et al. 2008).

To compound matters, the tsunami hit the Fukushima Daiichi nuclear plant. Again, there had been precautions only against a much smaller tsunami, and the defenses were directly overrun. The earthquake took out the main power supply, and the emergency generators were in the basement, which was immediately flooded. With no power at all on site, the reactor cooling was inoperable, and a meltdown was the result – the worst nuclear disaster since Chernobyl. The area around the site is still an exclusion zone, and cleaning it up will take decades.

Estimates of the total economic loss from the Tohoku earthquake and tsunami range from \$250 to 350 billion, making it probably the single most expensive natural disaster ever. It raises difficult questions about preparedness. Evidently the affected settlements could have been better prepared; but fishing communities have to live on the coast. And is protecting a town with a 15 m high sea wall a realistic option?

Box-Out: The Ten Deadliest Earthquakes

A number of lists have appeared over the years purporting to give the ten earthquakes with the highest number of fatalities. Many of these are prone to easily avoidable errors, such as perpetuating fake earthquakes like the notorious 1737 Calcutta event (see Bilham 1994 for the refutation of this) or the 893 Ardebil (Iran) earthquake. However, compiling an accurate list is difficult, since for even relatively modern earthquakes, death tolls are often inaccurate, given the sheer difficulty of making a body count in the

aftermath of a major disaster (as witness the difficulty of estimating the death toll in the 2010 Haiti earthquake). The problem is greatly multiplied for historical earthquakes, where sources are vague, unspecific, or exaggerated, and in most cases, there was no census to begin with.

The earthquake generally agreed to be the deadliest of all time is the 1556 Shaanxi earthquake, with 830,000 deaths. This great earthquake ($M \sim 8$) affected an area where many people were living in loess caves, which collapsed, burying the inhabitants.

The second deadliest is probably the 1976 Tangshan disaster. The death toll from this event has been a matter of controversy; the earthquake occurred during the Cultural Revolution in China, when news about disasters was generally suppressed. Shortly after the earthquake, a suspiciously accurate figure of 655,237 deaths appeared in the Hong Kong media (South China Morning Post, 5 Jan 1977). The official death toll later released was 242,419 (Chen 1988), though Marza (2004) suggests the true figure may have been over a million.

There are a number of earthquakes with death tolls in the region of 200,000–300,000 that are hard to discriminate between. Willis (1928) attributes 260,000 deaths to the Syrian earthquake of 115, but a comprehensive review of the sources by Ambraseys (2009) shows that while the death toll must have been very high, the total figure is unknown. There are several candidates for third place. The 1920 Ningxia earthquake killed 235,502 according to Utsu (2002) and 160,000 according to Tiedemann (1992). The official death toll of the 26 December 2004 (9.2 Mw) Sumatran earthquake is 227,898, mostly from the tsunami. The 1139 earthquake in Ganja, Azerbaijan, is considered by Ambraseys and Adams (1989) to have killed 230,000, a figure rejected by Guidoboni and Comastri (2005) as exaggerated (considering the total population of the affected area). Finally, the 12 January 2010 Haiti earthquake, at the time of writing, is believed to have killed around 220,000–230,000.

Events with death tolls around 200,000 include another Chinese earthquake, in Shanxi province in 1303, with a death toll around 200,000 (Fu et al. 2005), and the 856 Qumis earthquake in Iran, believed to have killed around 200,000 (Ambraseys and Melville 1982).

Next highest is undoubtedly the 1923 Kanto (Japan) earthquake with 143,000. The only other earthquake (leaving aside events with very doubtful high death

(continued)

tolls) with attributed deaths over 100,000 is the 1138 Aleppo earthquake, but this is another case where, according to Ambraseys (2009), the actual figure is quite unknown (Ambraseys 1962 gives 130,000).

If one removed 1138 and 1139 from the list as too doubtful, the next two events would be the Sichuan earthquake of 2008 with 87,587 and the 1908 Messina earthquake in Southern Italy (82,000).

This gives us the following list (all magnitudes are moment magnitude, Mw):

1.	23 January 1556	~8	Shaanxi (830,000)
2.	27 July 1976	7.5	Tangshan (240,000)
3.	16 December 1920	7.8	Ningxia (235,000)
4.	26 December 2004	9.2	Sumatra (230,000)
5.	12 January 2010	7.0	Haiti (230,000)
6.	17 September 1303	~8	Shanxi (200,000)
7.	22 December 856	~7	Qumis (200,000)
8.	25 September 1139	~7	Azerbaijan (high)
9.	1 September 1923	7.9	Kanto (143,000)
10.	15 October 1138	~7	Aleppo (130,000)

Numbers of fatalities are rounded to the nearest thousand; the precise ranking is obviously conjectural, as the figures are really only indicative of general loss levels. The distribution is shown in Fig. 1

Box-Out: The Ten Largest Earthquakes

Listing the ten largest earthquakes presents different problems. For the period since 1900, it is possible, at least in theory, to provide indisputable magnitude values from instrumental data, although figures are not precise for the very largest events. For the pre-instrumental era, the situation is much harder. Early attempts to convert historical data into estimates of magnitude tended to rely on maximum intensity; however, this rapidly saturates in large earthquakes. More sophisticated methods based on intensity data fields are available (e.g., Sibol et al. 1987), but these are unlikely to be accurate for very large events (the lack of calibration is one problem).

Earthquakes around the 9.0 Mw mark are necessarily subduction events – only large subduction thrust planes can provide large enough rupture areas to accommodate the vast energies required. Estimation of magnitude from non-instrumental data in such cases cannot rely on intensity distribution, which is liable to be incomplete, but really needs to be based on estimating rupture area and displacement. It was possible, for instance, on the morning of 26 December 2004, to see at once that the great Sumatran earthquake was at least 9 Mw just by looking at the huge extent of

(continued)

Great Earthquakes, Fig. 1 Map of the ten deadliest earthquakes in history

the aftershock distribution, which stretched for over 1000 km.

Since 1900, one can at least be certain that the catalogue for very large earthquakes is complete. Taking the Centennial Catalogue of Engdahl and Villaseñor 2002 as a basis, one can list the ten largest earthquakes since 1900 as follows (all magnitudes are moment magnitude, M_w):

1.	22 May 1960	9.6	Chile
2=.	28 March 1964	9.2	Alaska
2=.	26 December 2004	9.2	Sumatra
4.	9 March 1957	9.1	Andreanof Islands
5=.	11 March 2011	9.0	Tohoku
5=.	4 November 1952	9.0	Kamchatka
7=.	31 January 1906	8.8	Colombia-Ecuador
7=.	27 February 2010	8.8	Chile
9=.	11 November 1922	8.7	Chile
9=.	28 March 2005	8.7	Sumatra

The 2005 Sumatra earthquake, while not strictly an aftershock of the 26 December 2004 event, was certainly triggered by it. It was a very strange experience to be telling journalists that it was “only” 8.7 and small in comparison to the Boxing Day earthquake. It is somewhat remarkable that all the magnitude 9s in the

twentieth century, accounting for most of the seismic energy release of the whole century, occurred in the space of just 12 years, from 1952 to 1964. The years 2004–2011 appear to making a similar spike in the energy release record.

The distribution is shown in Fig. 2, which shows a very different pattern from Fig. 1. The 2004 Sumatra earthquake is the only one to appear on both lists. This should emphasize that the deadliness of an earthquake generally owes more to its location with respect to population centers, than to its size.

Summary

Two lists of earthquakes are presented here, the ten largest known earthquakes in historical times and the ten deadliest in terms of reported fatalities. The lists have marked differences, since a very large earthquake in a remote area will not kill many and a moderate earthquake in a heavily populated area may kill many, especially where building standards are low. Four case studies are presented of great earthquakes that have left a particular legacy.

Heat and Ground Water Flow

Vincenzo Pasquale, Massimo Verdoya and Paolo Chiozzi
Department of Earth, Environment and Life Sciences,
University of Genoa, Genoa, Italy

Definition

Aquifer	Permeable underground that can store or transmit water.
Heat advection	Heat transfer by water motion due to pressure gradient.
Heat convection	Heat transfer by water motion due to density gradient.

Energy Equation for Ground Water Flow

The basic theory of heat and ground water flow is similar to other diffusion theories. The energy equation governing the mechanism of heat transfer in addition to water flow is expressed as

$$\rho c \frac{\partial T}{\partial t} = k \nabla^2 T - \rho_w c_w (u \cdot \nabla T) \quad (1)$$

where c , ρ , and k are the water-rock matrix specific heat, density, and thermal conductivity, respectively, t is the time, $\rho_w c_w$ is the volumetric heat capacity of water, and ∇^2 is the Laplace operator. The term $u \cdot \nabla T$ is the scalar product of the Darcy velocity u , or volumetric flow rate of water per unit area, and the temperature gradient ∇T . Equation 1 neglects heat sources and considers thermal conductivity as isotropic and temperature-independent. Moreover, it assumes that rock and water are in thermal equilibrium (see e.g., Turcotte and Schubert 2002; Pasquale et al. 2017).

The water displacement is linearly proportional to the driving force given by pressure and inversely proportional to the resistance due to water viscosity and type of interstices through which water flows. Darcy's law describes ground water flow by stating that the Darcy velocity u is connected with water pressure p in the form

$$u = -\frac{\kappa_p}{\eta_w} \nabla(p + \rho_w g z) = -\frac{\kappa_p \rho_w g}{\eta_w} \nabla H_h = -\lambda_c \nabla H_h \quad (2)$$

where κ_p is the permeability, η_w and ρ_w are the water dynamic viscosity and density, respectively, $H_h = z + p/(\rho_w g)$ is the hydraulic head, z is the elevation above a standard datum, g is the acceleration due to gravity, $\lambda_c = \kappa_p \rho_w g / \eta_w$ is the hydraulic conductivity. When ground water flow is caused only by an externally applied pressure gradient, the heat transfer mechanism is referred to as advection. If the flow is driven by buoyancy effect (i.e., variation in density caused by temperature gradient), the mechanism is called thermal convection.

In case of steady heat and water flows and only vertical heat transport (the horizontal temperature gradient is negligible), substitution of Eq. 2 into Eq. 1 gives

$$\frac{d^2 T}{dz^2} = \frac{\rho_w c_w \kappa_p}{k \eta_w} \left[\frac{d}{dz} (p + \rho_w g z) + g z \frac{d\rho_w}{dz} \right] \frac{dT}{dz} \quad (3)$$

where ρ_w is a function of depth z . By introducing in this equation the hydraulic head and the expansion coefficient of water $\alpha_w = (d\rho_w/dT)/\rho_w$, one obtains

$$\frac{d^2 T}{dz^2} = \frac{\rho_w^2 c_w g \kappa_p}{k \eta_w} \left(\frac{dH_h}{dz} + \alpha_w z \frac{dT}{dz} \right) \frac{dT}{dz} \quad (4)$$

This one-dimensional equation contains terms expressing the conductive heat transfer, heat advection, and thermal convection in a uniform, isotropic, homogenous aquifer.

Heat Advection

In case of advection the buoyancy force is negligible, and Eq. 4 becomes

$$\frac{d^2T}{dz^2} - \frac{c_w \rho_w u_z}{k} \frac{dT}{dz} = 0 \quad (5)$$

with u_z the Darcy velocity in the vertical direction (positive downwards). The solution of Eq. 5 is

$$T = T_1 + (T_2 - T_1) \frac{\exp(\beta_z z/h) - 1}{\exp \beta_z - 1} \quad (6)$$

where $\beta_z = c_w \rho_w u_z h/k$ is a dimensionless parameter, which may be positive or negative depending on whether u_z is downward or upward, and T_1 and T_2 are the temperatures at the top and at the bottom of the vertical distance h within the aquifer (Fig. 1). Equation 6 is valid for steady-state thermal conditions and for a flow rate assumed constant and so slow that thermal equilibrium between water and rock matrix is maintained.

More generally, because surface topographic relief usually exists across an aquifer, heat and water flow, particularly in a sloping semi-confining aquifer, is neither purely horizontal nor purely vertical. In this case, Lu and Ge (1996) demonstrated that the solution for a two-dimensional flow is an extension of Eq. 5. Assuming a linear variation of temperature along the horizontal direction, in the left-hand member of the equation we must add the term $-\Gamma_o(\beta_o/h)$ that accounts for the constant horizontal flow of heat and water. Therefore, we have

$$\frac{d^2T}{dz^2} - \frac{\beta_z}{h} \frac{dT}{dz} - \frac{\beta_o}{h} \Gamma_o = 0 \quad (7)$$

where $\beta_o = c_w \rho_w u_o h/k$, and Γ_o and u_o are the horizontal components of the temperature gradient and the Darcy velocity, respectively. The gradient Γ_o is taken positive (or negative) when the heat flow is leftward (or rightward). The solution of Eq. 7 is

$$T = T_1 + (T_2 - T_1) \left[\frac{\exp(\beta_z z/h) - 1}{\exp \beta_z - 1} + \frac{\Gamma_o \beta_o}{\Gamma_z \beta_z} \left(\frac{\exp(\beta_z z/h) - 1}{\exp \beta_z - 1} - \frac{z}{h} \right) \right] \quad (8)$$

where Γ_z is the vertical temperature gradient. In the absence of horizontal heat or water flow ($\Gamma_o = 0$ or $u_o = 0$), Eq. 8 reduces to Eq. 6. Ratio $(T - T_1)/(T_2 - T_1)$ versus z/h for $(\Gamma_o \beta_o)/(\Gamma_z \beta_z)$ and different β_z is shown in Fig. 2.

Reiter (2001) suggested that the analysis of the thermal effect of ground water can be practicable by comparing the temperature gradient Γ_z with temperature and depth. Integrating Eq. 7 once, we obtain

$$\Gamma_z = \frac{\beta_z T}{h} + \frac{\beta_o \Gamma_o z}{h} + C \quad (9)$$

where C is the integration constant. Equation 9 can be seen as a plane whose slopes in relation with the axes of temperature and depth contain information on the vertical and horizontal components of the Darcy velocity (Fig. 3). When one component of water flow is dominant, Eq. 9 reduces to a straight line. Then, the temperature gradient is only a function of depth for $u_z = 0$, while it is a function of temperature for negligible horizontal flow.

Heat and Ground Water Flow, Fig. 1 Ratio $(T - T_1)/(T_2 - T_1)$ versus z/h for different values of β_z (water downward) and $-\beta_z$ (upward water)

Heat and Ground Water Flow, Fig. 2 Ratio $(T - T_1)/(T_2 - T_1)$ versus z/h for $(\Gamma_o \beta_o)/(\Gamma_z \beta_z) = 0.2$ (hatched curve), $(\Gamma_o \beta_o)/(\Gamma_z \beta_z) = -0.2$ (solid curve) and different β_z

Heat and Ground Water Flow, Fig. 3 The plane containing the temperature gradient versus depth and temperature (Eq. 9)

The quantities β_z and β_o measure the relative efficiency of an aquifer for the simultaneous heat transport by both water flow and pure conduction. They appear to be analogues of the thermal Péclet number, which quantifies the potential for advection to perturb the temperature-depth distribution. The vertical Péclet number Pe_z can be expressed as the ratio of the advected heat flow q_{ad} and the conducted heat flow q_c over a characteristic length L

$$Pe_z = \frac{q_{ad}}{q_c} = \frac{\rho_w c_w |u_z| (T_2 - T_1)}{k (T_2 - T_1)/L} = \frac{\rho_w c_w |u_z| L}{k} \quad (10)$$

When $Pe_z \gg 1$ vertical advection dominates, while the conductive component prevails for $Pe_z \ll 1$ (Clauser and Villinger 1990). The length L can be chosen in many ways and is often selected depending on the scale of the flow system. Normally, it is assumed to correspond to the thickness of the aquifer. By substituting u_o for u_z into Eq. 10, it is possible to derive also the horizontal Péclet number.

The foregoing analytical solutions for heat and water flow can be applied to borehole temperature data, recorded by means of high precision equipment. The analysis procedure, which consists in matching temperature and temperature gradient data with theoretical curves obtained from Eqs. 6, 8, and 9, leads to the estimation of the Darcy velocity (see for details, Verdoya et al. 2008; Pasquale et al. 2010).

Hydrothermal Systems

There are special analytical solutions that provide estimates of the water temperature along flow paths like those occurring in an advection-dominated hydrothermal systems. An analysis of the heat transported by the water from the recharge to the discharge area can be carried out by assuming geometry and hydraulic properties of the hydrothermal system.

Heat and Ground Water Flow, Fig. 4 Sketch of a horizontal aquifer

Figure 4 sketches a horizontal water path of thickness h_o , at depth H below the surface, in which water moves at a Darcy velocity u . The water temperature T varies only along the horizontal x -axis. In a section dx of the aquifer, during time $dt = dx/u$, the heat per unit width that enters is $Q_a = q dx^2/u$, whereas the heat flowing out is $Q_b = k (T - T_o) dx^2/(H u)$, where q is geothermal flow beneath the aquifer, T_o the temperature at the surface and k the water-rock matrix thermal conductivity, assumed to be uniform with depth. The gain of heat $Q = (Q_a - Q_b)$ is

$$Q = \left(\frac{q}{u} - k \frac{T - T_o}{H u} \right) dx^2 \quad (11)$$

and the corresponding increase of water temperature is $dT = Q/(\rho_w c_w h_o \sigma dx)$, where σ is the effective porosity. Thus, along the direction x , we obtain

$$\frac{dT}{dx} = \left(q - k \frac{T - T_o}{H} \right) \frac{1}{\rho_w c_w \sigma h_o u} \quad (12)$$

At $x = 0$, if the temperature $T = T_i$, the normalized temperature ψ as a function of X is given by (Schoeller 1962; Pasquale et al. 2011)

$$\psi(X) = \exp(-X/\alpha) \quad (13)$$

where $\psi(X) = (T(x) - T_H)/(T_i - T_H)$, $X = x/H$ and T_H is the background temperature at depth H given by $T_o + q H/k$ (Fig. 5). The parameter $\alpha = c_w \rho_w u h_o \sigma/k$ is dimensionless. This approach assumes that water and the aquifer inner boundaries have the same temperature because of the large thermal resistance of the rocks, the slow water flow, and the large contact surface.

In a recharge area, the ground water may seep through a descending flow path. The ground water temperature along the sloping flow path is (Schoeller 1962; Pasquale et al. 2011)

$$\phi(x) = \frac{\Gamma_z x}{\cot i + \alpha} \quad (14)$$

Heat and Ground Water Flow, Fig. 5 $\psi(X)$ for different values of α along a horizontal aquifer

Heat and Ground Water Flow, Fig. 6 Scheme of an ascending aquifer

where $\varphi(x) = T(x) - T_i$ is the temperature of water along the horizontal x axis, T_i is the temperature of water at the beginning of the flow path, Γ_z is the background vertical temperature gradient, and i is the slope of the aquifer.

For ground water flow ascending to the surface, like, e.g., in a discharge area (Fig. 6), the water temperature as a function of z is given by

$$\vartheta(z) = -\Gamma_z z + (T_i - T_H) \exp\left(-\frac{2z}{R \alpha \sin i}\right) + \frac{\Gamma_z R \alpha \sin i}{2} \left[1 - \exp\left(-\frac{2z}{R \alpha \sin i}\right)\right] \quad (15)$$

where $\vartheta(z) = T(z) - T_H$ and T_H is the unperturbed temperature at depth $H(z = 0)$. The term $R = h_o e^5$ represents the thickness of the medium surrounding the aquifer and perturbed by the heat exchange. If we assume the discharge area as a single subvertical cylindrical conduit, by replacing h_o with the radius r of the conduit, the temperature is given by

Heat and Ground Water Flow, Fig. 7 Subsurface temperature, water temperature and water travel time in the hydrothermal system of Acqui Terme (NW Italy) (after Pasquale et al. 2011). $T_o = 12.5$ °C and $T_s = 70.0$ °C are the water temperature values in the recharge area and at the hot spring, respectively

$$Y(z) = -\Gamma_z z + \frac{\Gamma_z \sin i}{A} \left[1 - \exp\left(-\frac{A z}{\sin i}\right)\right] \quad (16)$$

where $Y(z) = T(z) - T_H$ is the water temperature as a function of depth and $A = 2 k/[c_w \rho_w u r^2 \ln(R/r)]$.

An example of the temperature and the water travel time estimated by means of Eqs. 13, 14, 15, and 16 is shown in Fig. 7. From the recharge area of the hydrothermal system, located at about 14 km from the hot spring (70 °C), meteoric water heats up due to the background geothermal flow while descending and horizontally flowing within the fractured basement. After the maximum temperature (110 °C) is reached (at a depth of 2800 m), water rapidly rises to the spring, through a sub-vertical fault. This scheme of deep ground water flow is consistent with geochemical data, and with borehole temperature logs. The water residence time within the hydrothermal system is about 300 years.

Heat Convection

In high-temperature hydrothermal systems, typically occurring in volcanic areas, convection is the dominating heat-transfer mechanism. Convection can occur also in deep carbonate reservoirs hosting low-temperature thermal water. A convenient way to analyze the occurrence of heat convection in an aquifer heated from below is the dimensionless Rayleigh number, R_a , defined as

$$R_a = \frac{g \alpha_w \rho_w c_w \kappa_p L \Delta T}{v_w k} \quad (17)$$

where v_w is kinematic viscosity of the saturating water, L is the length over which convection occurs, ΔT is the temperature difference between the top and bottom of this length interval. In the temperature range expected within an aquifer,

v_w can be evaluated with the following expressions (Holzbecher 1998)

$$v_w = 10^{-3} [1 + 0.015512 (T - 20)]^{-1.572} \quad 40^\circ \text{C} < T < 100^\circ \text{C} \quad (18)$$

$$v_w = 0.2414 \rho_w \times 10^{\frac{247.8}{T+133.15}} \times 10^{-4} \quad 100^\circ \text{C} < T < 300^\circ \text{C} \quad (19)$$

where water density ρ_w varies with temperature T as

$$\rho_w = 1000 \left[1 - \frac{(T - 3.9863^2) (T + 288.9414)}{508929.2 (T + 68.12963)} \right] \quad (20)$$

Therefore, convection occurs under appropriate thermal and permeability conditions. In practical terms, the Rayleigh number helps to differentiate between purely conductive systems, where isothermal constant density models are applicable, and low-grade hydrothermal systems, where nonisothermal models must be used. When the Rayleigh number exceeds the critical value of $4\pi^2$, convection starts and groundwater may form convective cells.

By analyzing thermal records from hydrocarbon exploration wells, Pasquale et al. (2013) provided evidence of thermal convection in the deep carbonate reservoir of the eastern Po Plain (Italy). Figure 8 shows the temperature-depth distribution as inferred through inversion of thermal data together with the temperature simply extrapolated from the observed thermal gradient. In the uppermost sedimentary layers, the inferred temperature matches the observed temperature, whereas within the Palaeogene layer and in the Mesozoic reservoir there are significant differences. As the thermal conductivity variation is small within the sedimentary sequence and the hydrogeological characteristics (including litho-stratigraphic sequences and structural setting) hardly permit advection, thermal convection can account for these differences. Convection could cause a decrease of temperature gradient in the reservoir and a significant increase in the overlying Palaeogene low-permeability unit.

The potential for thermal convection to take place within the reservoir can be quantified with Eq. 17. By assuming that $R_a = 4\pi^2$, $g = 9.8 \text{ m s}^{-2}$, $\rho_w c_w = 4032 \text{ kJ m}^{-3} \text{ K}^{-1}$, $k = 3.1 \text{ W m}^{-1} \text{ K}^{-1}$, $\alpha_w = 0.82 \times 10^{-3} \text{ K}^{-1}$, $v_w = 2.60 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$, and that all the parameters are independent from pressure, Eq. 17 becomes

$$\left(\frac{dT}{dz} \right)_{\min} = \frac{9.82 \times 10^{-10}}{\kappa_p L^2} \quad (21)$$

where the length L of convection is the thickness of the reservoir. Equation 21 provides the minimum temperature gradient

Heat and Ground Water Flow, Fig. 8 Temperature versus depth as inferred from inversion of temperature recorded in petroleum wells (broken line) and by extrapolating the observed temperature gradient (continuous line). Arrows indicate likely thermal convection in the carbonate reservoir

required for convection. For typical values of temperature gradient (14 mK m^{-1}) and thickness (5 km) of the Mesozoic carbonate reservoir, the inferred permeability, k_p , is larger than $3 \times 10^{-15} \text{ m}^2$. This value is consistent with the minimum range of $5 \times 10^{-17} - 10^{-15} \text{ m}^2$ required for thermal convection to occur in porous rocks (Manning and Ingebritsen 1999).

Conclusions

Although modeling of heat transfer in aquifers of complex structure with particular boundary conditions is often addressed by means numerical methods (see e.g., Haenel et al. 1988; Bartels et al. 2003), in mid-low permeability aquifers of simple geometry, the analytical methods presented here can quantitatively describe the heat transport coupled with single-phase water flow.

Heat Flow Determinations, Continental

John H. Sass (Deceased)¹ and Graeme Beardsmore^{2,3}

²University of Melbourne, Parkville, VIC, Australia

³Hot Dry Rocks Pty Ltd, Windsor, VIC, Australia

Definition

Continental heat flow is the flux density of heat being conducted to the surface of continents. It is expressed as mW m^{-2} . Heat flow is calculated as the product of temperature gradient (mK m^{-1} or $^{\circ}\text{C per km}$ – a scale appropriate to the dimensions of geological formations) and thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$).

Introduction

Terrestrial heat flow, Q , is estimated from the product of temperature gradient (Γ) and thermal conductivity (K), according to:

$$Q = K\Gamma \quad (1)$$

In practice, Γ is derived from point measurements of temperature at two or more discrete depths. K can be determined in situ, but it is acceptable and often more practical to measure it on samples brought to the surface, either in the field or in a laboratory.

Beardsmore and Cull (2001) reviewed several options for solving Eq. 1 using discrete data sets. These usually involve combining the harmonic mean thermal conductivity with the average temperature gradient over discrete intervals of the temperature profiles. Where there is significant thermal conductivity stratification, the “Bullard plot” is a useful method for calculating average heat flow (see Fig. 1). In this method, temperature is plotted against integrated thermal resistance, R , where $R = dz/K$, dz being the thickness of the interval with mean conductivity K . If heat flow is constant with depth, the relation is linear and the slope of the line is the heat flow.

Uncertainty is inherent in heat flow determinations:

- The average temperature gradient and the average thermal conductivity must be determined over the same depth interval for a precise determination of heat flow.
- Temperature gradient estimates become more precise by averaging over greater depth intervals, but thermal conductivity estimates become less precise.
- It is rarely practical to measure thermal conductivity continuously over an entire depth interval, so measured samples must be assumed to also represent unsampled sections.
- The transient thermal disturbance due to seasonal surface temperature cycles may extend to a depth of several tens of meters, so stable results can only be obtained at greater depths.
- The diffusion of historical step changes in surface temperature (e.g., from land clearance or the retreat of glaciation) may affect heat flow determinations down to hundreds of meters or more.
- Continental heat flow might not be parallel to vertical boreholes because heat flow is affected by significant lateral and temporal variations in surface temperature, especially when compared to determinations of heat flow beneath the oceans.
- Heat flow on the continents is also more likely than oceanic heat flow to be distorted by heat refraction by near-surface variations in geological structures and topography.

Heat Flow Determinations, Continental, Fig. 1 A hypothetical rock sequence with thermal properties and unit thicknesses as indicated. The thermal resistance, R , of each unit is equal to its thickness, dz , divided by its thermal conductivity, K . A temperature–depth profile through the

sequence is nonlinear, but a Bullard plot of temperature versus integrated thermal resistance is linear with slope equal to the heat flow. Heat flow in this example is 65 mW m^{-2}

Derived heat flow values may vary depending on the depth and sampling strategy of the survey, so careful thought should precede the design of any survey aimed at quantifying regional continental heat flow.

Temperature

The earliest measurements of temperature beneath the earth's surface were obtained from mines and tunnels. As exploratory drilling for petroleum and minerals became widespread, temperature profiles obtained in boreholes became the most common means of determining temperature gradients within the earth. Electronic thermometers deployed on a wire line are the most common tool for measuring temperatures within the earth, although the use of fiber optic systems is increasing.

The accuracy and precision of temperature gradient estimates depend on the accuracy and precision of temperature and depth measurements. Best practice calls for a precision of $\sim 0.001 \text{ K}$ at $\sim 1 \text{ m}$ intervals over several hundred meters. Temperature sensor types appropriate for borehole measurements include the following:

- **Thermistors:** A thermistor is a bead of sintered metallic oxide, commonly germanium. The electrical resistance across a thermistor decreases strongly with increasing

temperature (typically -4% per K between 0°C and 100°C). Simple electrical resistance measurement devices such as off-balance Wheatstone bridges and $4\frac{1}{2}$ digit digital multimeters (DMMs) are sufficient for 1 mK temperature precision (McGee and Thomas 1988). Thermistor probes for use in “normal” continental borehole environments usually have a resistance of between 3 and 100 k Ω at 25°C and provide precise estimates of temperature between about 0°C and 80°C , above which their temperature sensitivity drops off because of low resistance. Each thermistor has a unique resistance–temperature response so must be individually calibrated.

- **Platinum “resistance temperature detectors” (RTDs):** The key component of platinum RTDs is a length of pure platinum wire. The electrical resistance of platinum wire increases predictably with increasing temperature, although the response is less sensitive than that of thermistors. Depending upon their construction and configuration, platinum RTDs can operate successfully up to 500°C (see Tew and Strouse 2001, for principles and standards). 1 mK temperature precision can be obtained with RTDs if $6\frac{1}{2}$ digit DMMs are employed for readouts. RTD probes for continental borehole environments typically have a resistance of 1 or 2 k Ω at 20°C . One advantage over thermistors is that RTD sensors are interchangeable without the need for individual calibration.

- Diodes: Effective temperature sensors can be constructed from ordinary semiconductor diodes. Such sensors have linear voltage or current responses with temperature, are of relatively small size, operate over a limited temperature range (typically -40°C to $+120^{\circ}\text{C}$), are relatively cheap, and can achieve equivalent precision and accuracy to thermistors and RTDs if individually calibrated. Diode temperature sensors tend to be less robust (electrically and physically) than other sensor types, which tends to rule them out of most borehole applications. For stationary applications, however, commercial semiconductor sensors are available that provide an output signal as a voltage, a current, a resistance, or as digital data.
- Fiber optic “distributed temperature sensors” (DTS): Temperature measurement using fiber optic cables employs the phenomenon of “Raman scattering” of laser light. About one in ten million of the photons directed along the cable with a constant wavelength scatter in such a way that their wavelength either increases or decreases. The intensity of the scattered band with shorter wavelength is temperature dependent, while the intensity of the longer wavelength band is independent of temperature. The local temperature of the cable is derived from the ratio of the shorter to longer wavelength intensities. The location along the cable is inferred from the time elapsed between the incident laser pulse and the detection of the scattered signals. Temperature resolution increases relative to the number of repeated pulses over which each measurement is averaged. Commercially available instruments can achieve temperature accuracy of $\sim 1^{\circ}\text{C}$, temperature resolution of $\sim 0.01^{\circ}\text{C}$, and depth accuracy and resolution of $\sim 1\text{ m}$ (Selker et al. 2006). Instantaneous records of temperature distribution along continuous lengths of cable up to 30,000 m can be obtained within a fraction of a minute. Förster et al. (1997) presented a comparison between fiber-optic and conventional temperature logs.
- Down-hole oscillator with dual-conductor logging cable: Resistance-based elements can be incorporated into an oscillator circuit to create a frequency–temperature dependence. With a power source and amplifier included with the oscillator circuit in the probe, the frequency of the oscillating output current can be monitored in real time from the surface via the dual conductors, unaffected by leakage resistance between conductors. Doig et al. (1961) reported precision of 0.05°C .
- “Memory” tools: Memory, or “computer,” tools are fully self-contained probes including power source, memory, clock, and temperature sensor. Some also include onboard pressure gauges as a proxy for a depth sensor. Memory tools are initialized at the surface and deployed downhole on a single wire slickline. They record time–temperature data at preprogrammed intervals and store the data in onboard memory. The data are downloaded from the tool after it is recovered to the surface (Suto et al. 2008). Time–depth data are required to convert the time–temperature data into a depth–temperature log. Time–depth data can be recorded at the winch or wellhead during deployment or can be interpreted from time–pressure data if the probe is fitted with a pressure gauge.
- Fiber optic DTS: DTS systems include a length of fiber optic cable weighted on the end, a laser source, and a spectrometer to detect and quantify the frequency and intensity of back-scattered light. Henniges et al. (2005) described the deployment of fiber optic cable systems for both synoptic temperature logs and long-term monitoring of temperature.

The relative uncertainty in temperature gradient is the sum of the relative uncertainties in temperature differential and depth interval. These uncertainties decrease with increasing depth interval. In most cases, temperature gradient determined over an interval of several tens of meters provides relative uncertainty better than 5%.

Borehole Temperature Systems include the following types:

- Four-conductor logging cable from the sensor probe to the surface: Typically, one pair of conductors forms a closed loop while the other pair connects through the sensor probe. This provides for accurate measurement of the resistance of the temperature sensor in the probe by quantifying the contribution of the cable to the total resistance. It requires that the leakage resistance between conductors be effectively infinite, a specification that can be met by manufacturers of geophysical logging cables. The relatively high resistance of thermistors with respect to typical logging cable makes them the most suitable sensors for these systems.

Thermal Conductivity

The International Society for Rock Mechanics and Rock Engineering recommends three different methods for measuring thermal conductivity on samples at atmospheric pressure (Popov et al. 2016): (a) steady state divided bar, (b) transient point-, line-, or plane-source, and (c) optical scanning.

Lodge (1878) originally introduced the concept of the divided bar. The device is essentially a vertical “stack” within which the temperature drop across a standard substance is compared with that across a specimen of unknown thermal conductivity. By design, it measures uniaxial conductivity, so specimens can be prepared to measure conductivity along any

axis of interest. Benfield (1939) and Birch and Clark (1940) described early divided bars at Cambridge and Harvard universities, respectively, with constant heat sources at the top of their stacks and isothermal sinks at their bases. Evolution to a constant temperature difference regulated by water baths in the 1950s (Beck 1957) resulted in more rapid measurements. In the late 1960s, the divided bar was adapted to the measurement of the thermal conductivity of rock fragments, by far the most common source of material (Sass et al. 1971). Substitution of Peltier devices for the constant temperature water baths provided hitherto unattainable portability, economy, and speed of measurement from 2010 (Antriasian 2010; Fig. 2).

With transient methods, heat is applied to a rock at a known rate by an element approximating an ideal point, line, or surface. The rock warms in response to the heater at a rate dependent on its thermal conductivity. Thermal conductivity can be deduced by analyzing the temperature–time curve of the heater element or a nearby point. In general, more conductive rocks draw heat away from the element at a greater rate and result in a slower increase in temperature.

Transient methods can be applied in a permanent laboratory, in mobile field laboratories, or under certain conditions, within boreholes. Jaeger (1959) described the mathematical

framework for measuring thermal conductivity with linear and cylindrical heat sources embedded in materials approximating infinite solids, such as needle-like probes inserted into rocks. Vacquier (1985) extended the method to linear sources applied to the flat surface of an infinite half-space. Compared to the divided bar, transient source methods present difficulties in characterizing uniaxial (e.g., vertical) conductivity because they conduct heat radially, rather than linearly, in all directions away from the source. In homogenous sequences, conductivity is the same in all directions, but the values may be significantly different in heterogeneous sequences. Horai (1971) described the adaption of line-source technique to measure the thermal conductivity of rock fragments. Grubbe et al. (1983) showed that if large enough specimens are available, the principal axial values of conductivity can be derived by making several measurements with the source in different orientations. Sass et al. (1984) described the United States Geological Survey's (USGS) versions of line-source techniques in detail. Transient source units available commercially include QTM-710/700 (KEM undated), TLS-100 (Thermtest undated), and C-Therm TCi (C-Therm Technology 2018).

In the 1980s, Popov et al. (1983) described a rapid, non-destructive method for measuring the thermal conductivity of rocks along continuous lines using an optical scanning technique. Rock faces are painted black and aligned with known standard materials along a track. A unit containing a laser heat source and infrared temperature sensors moves beneath the specimens at a constant speed, focusing the laser onto the painted surfaces. The radiometer measures the rise in temperature of the specimens at a constant time and distance after the heating due to the applied laser pulse. The temperature rise is related to the thermal conductivity of the specimen.

A three-way comparison between a divided bar operated by the USGS, a line-source half-space apparatus operated by GeoForschungsZentrum (GFZ) in Germany, and an optical scanner operated by Popov in Russia showed close agreement over a variety of crystalline rock types representing a wide range of thermal conductivity values (Popov et al. 1999).

In Situ Thermal Conductivity Measurement in Boreholes

The in situ measurement of thermal conductivity in vertical boreholes generally presents great experimental and logistical difficulties. In anisotropic rocks, it also measures conductivity radially away from the borehole so that independent measurements of anisotropy on core are required to calculate vertical conductivity. Conductivity was measured over a ~2 m interval of the KTB pilot core hole using an in situ cylindrical heat source (Burkhardt et al. 1990) as a demonstration of the feasibility of the method. The organization Posiva Oy in Finland has done much to develop the technique since the late 1990s.

During the boom in geothermal exploration in the mid- to late 1970s, the importance of determining heat flow as well as

Heat Flow Determinations, Continental, Fig. 2 A commercial divided bar utilizing Peltier devices as heat source/sink. (Photo courtesy of Hot Dry Rocks Pty Ltd, Australia)

temperature gradients became apparent. This was coupled with concerns over the security of exploration wells in competitive lease areas. To address these issues, the Geothermal Studies Project of the US Geological Survey developed a method for determining temperature gradient, thermal conductivity, and thus, heat flow in situ over discrete intervals during the drilling process (Sass et al. 1981).

Details of the technology can be found in Sass et al. (1979) with the caveat that the electronics and computer hardware described in that reference have since been superseded.

More recently, Freifeld et al. (2008) demonstrated thermal conductivity profiling of entire boreholes by coupling a down-hole line-source heating loop with a fiber optic DTS system.

Sampling

Thermal conductivity can rarely be practically measured over the full interval of interest. Certain sampling protocols must be devised and followed to estimate the conductivity over significant depth intervals. This may involve:

- Characterizing the conductivity of individual geological formations where these are largely homogenous
- Selecting samples from evenly spaced intervals as a “random” sampling strategy
- Measuring mixtures of chips from sequential depth intervals

Many studies have shown that the standard deviation of conductivity measurements on samples from seemingly homogenous formations can be as high as 30% of the mean. Measurements must be obtained from sufficient samples, therefore, to constrain the mean conductivity of the formation to within an acceptable standard error. Measurements on ten samples of a given homogenous formation should yield a mean conductivity within 10% of its true value.

Conductivity is temperature dependent and values measured in the laboratory should be corrected for in situ conditions especially for very deep wells, and in geothermal areas with high temperature gradients.

When no rock samples are available for measurement of thermal conductivity, estimates can be obtained from empirical relations between conductivity and well-log parameters or by choosing a “flux plate,” a layer of more than a few meters thickness composed of a rock type whose conductivity has been characterized by measurements elsewhere. See Blackwell and Steele (1989) for a review of these methods.

Summary

Heat flowing from the surface of the continents cannot be measured directly. It is calculated as the product of the

temperature gradient (most often measured in boreholes) and the thermal conductivity of the formation within which the temperature gradient was measured. Thermal conductivity can be measured in situ, but by far the majority of measurements are made on rock samples from the borehole, or from nearby outcrops of the relevant formations. To determine heat flow with a relative uncertainty better than 10%, temperature gradient should be determined over a minimum depth interval of tens of meters, with conductivity measured on ten or more samples from within that interval.

Temperatures are usually measured by electronic transducers deployed on multiconductor electrical cables or incorporated into “memory tools” that are lowered into the borehole on steel or alloy wires. Fiber optic cables can also be inserted into boreholes to provide synoptic temperature profiles or a time series of profiles.

A variety of techniques, based on both steady-state and transient heat flow, can be used to characterize the thermal conductivity of rock specimens. Optical scanning methods provide rapid profiles of thermal conductivity estimates along extended scan lines and are valuable reconnaissance tools complementary to divided bar and point- or line-source transient techniques.

The heat flow determined for any given location and depth interval might be strongly influenced by local spatial or temporal thermal disturbances and not represent regional heat flow conditions. Heat flow is most likely to represent regional conditions if determined within boreholes that have had time to thermally re-equilibrate to natural conditions within a volume of rock with relatively uniform properties over space and time. In practice, locations that best approximate such conditions have low topographic relief, minimal surface disturbance over prior decades or centuries, low rates of erosion or deposition, laterally homogenous geology, and minimal groundwater movement.

Heat Flow, Continental

Paul Morgan
Colorado Geological Survey, Denver, CO, USA

Synonyms

Heat flow; Heat flow density; Heat flux, land; Terrestrial heat flow

Definition

Heat flow	The outward flow of thermal energy by conduction from within the Earth through the solid surface of the Earth.
Continental heat flow	Heat flow from the continental crust or lithosphere, which are those portions of the plates that are not directly formed by seafloor spreading at mid-ocean ridges and are not generally subducted.

Introduction

Heat flow is a fundamental property of the Earth. The Earth is a heat engine that drives plate tectonics and intra-plate processes such as hot-spot volcanism unrelated to plate margins. Heat flow, the outward flow of thermal energy from within the Earth through the solid surface of the Earth, is a measure of the thermal energy that drives this heat engine. In addition, temperature in the Earth, which is closely related to heat flow, is a primary parameter controlling physical properties of materials within the Earth. In general, areas of high heat flow are underlain by higher temperatures, at least at shallow depth, than areas of low heat flow. We seek therefore to know the distribution of heat flow from the surface of the Earth and to understand the factors that control its variations.

The primary factor controlling the distribution of heat flow is the type of lithosphere, continental or oceanic. Continental lithosphere is generally relatively old (>500 Ma) and the dominant mechanism of heat transfer through this lithosphere is conduction. A significant portion of heat flow from this lithosphere is generated by radiogenic heat production in the continental crust. In contrast, oceanic lithosphere is young (<200 Ma), heat is convected into this lithosphere as it is formed at mid-ocean ridges and it has very little internal radiogenic heat production (see ► [“Heat Flow, Seafloor: Methods and Observations”](#)). A variety of geologic processes modify continental lithosphere and most of these processes also modify the thermal regime. In addition, the upper continental crust commonly hosts moving groundwater that redistributes heat in the upper crust. Thus, the long and complex history of continental lithosphere, significant and lateral variability in radiogenic heat generation, and redistribution of heat by groundwater combine to make continental heat flow heterogeneous.

Fourier’s Law

Under conditions of steady state, heat flow, q , is a function of thermal conductivity, K , and temperature, T , given by Fourier’s law:

$$q = -K\nabla T, \quad (1)$$

where ∇ is the gradient operator. This equation assumes that thermal conductivity is isotropic, that is, it does not change with direction. In general, spatial changes in thermal conductivity and anisotropy must be considered. The negative sign in the equation recognizes that heat flows from higher temperatures to lower temperatures and that flow of heat is in the opposite direction to the temperature gradient. On average, Earth heat flow is primarily vertical and the vertical component of heat flow, q_z , is commonly quoted:

$$q_z = -K \frac{\partial T}{\partial z}, \quad (2)$$

where z is depth. In practice, the subscript and negative sign are commonly omitted:

$$q = K \partial T / \partial z. \quad (2a)$$

The working units of q , K , and $\partial T / \partial z$ are mW m^{-2} , $\text{W m}^{-1} \text{ } ^\circ\text{C}^{-1}$ or $\text{W m}^{-1} \text{ K}^{-1}$, and $^\circ\text{C km}^{-1}$, respectively.

Under transient conditions the heat conduction equation in one dimension becomes:

$$\frac{\partial T}{\partial t} = \kappa \frac{\partial^2 T}{\partial z^2}, \quad (3)$$

where t is time and κ is thermal diffusivity, given by $\kappa = K/\rho c$, where ρ is density and c is specific heat. The general working units for t and κ are s and $\text{mm}^2 \text{ s}^{-1}$, although Ma and $\text{km}^2 \text{ Ma}^{-1}$ are also sometimes used.

If heat generation, A , is also included, the heat flow equation becomes:

$$\frac{\partial^2 T}{\partial z^2} - \frac{1}{\kappa} \frac{\partial T}{\partial t} + \frac{A}{K} = 0. \quad (4)$$

The working units for radiogenic heat generation, A , are $\mu\text{W m}^{-3}$.

Geothermal Gradient

The rate of increase in temperature with depth, $\partial T / \partial z$, is the *geothermal gradient*. This term is usually reserved for zones over which heat is transferred by conduction and the rate of increase in temperature with depth is linear (see ► [“Heat Flow Determinations, Continental”](#)), but if detailed temperature data are not available or gradients are estimated from oil-well bottom-hole temperatures, an approximate average geothermal gradient may be given. The profile of temperature plotted as a function of depth is the *geotherm*.

Geothermal gradients range from very low to near zero in fore-arc regions, the zones between subduction zones and their associated volcanic belts where heat is convected downward by the subducting lithosphere. Similarly, low gradients are found in zones of groundwater recharge. Gradients in excess of $20,000\text{ }^{\circ}\text{C km}^{-1}$ have been measured at one location in the upper few meters of the sediments beneath Yellowstone Lake inside the caldera of Yellowstone National Park, Wyoming, USA (Morgan et al. 1977), but such high gradients are buffered by the boiling point curve of water as soon as temperatures reach the boiling temperature at depth. Thus, there is a very wide range of geothermal gradients in the upper continental crust. Temperatures are ultimately controlled by the boiling point curve of water in the uppermost crust and then the solidus curves of the crust and mantle lithosphere, and temperatures at depth generally do not range as widely as shallow geothermal gradients might suggest. Thermal conductivity varies by a factor of about 5 in the main rock types that comprise the continental crust (see ► “Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat”): there is some variation in heat flow associated with changes in thermal conductivity, but the most significant variations in heat flow are accompanied by changes in geothermal gradient.

Sources of Heat

There are two sources of heat contributing to continental heat flow, heat that enters continental lithosphere from below, and heat generated within the continental lithosphere (see ► “Energy Budget of the Earth”). Although the Earth beneath the lithosphere has thermal energy that must ultimately be lost to the surface either through the lithosphere or in the process of the formation of new oceanic lithosphere at mid-oceanic ridges, there is no requirement where or when that heat must be lost, that is, there is no constant basal heat flux that flows into continental lithosphere. The thermal boundary condition at the base of the lithosphere is probably more accurately described as a constant temperature boundary, and this constant temperature may be maintained either by small-scale convection and/or lateral flow in the asthenosphere. Heat flow into the base of the lithosphere is then determined by the thermal conductivity structure of the lithosphere, the thickness of the lithosphere, heat production within the lithosphere, and its surface temperature. The resulting thermal profile is disrupted during major deformation of the lithosphere or changes in its boundary conditions.

By far the largest source of heat within the lithosphere is radiogenic heat production from the decay series of the unstable isotopes ^{232}Th , $^{235,238}\text{U}$, and ^{40}K . These isotopes all have half-lives of the same order as the age of the Earth and thus remain sufficiently abundant to be significant and continue to

decay at a rate that is significant in terms of heat production (see ► “Radiogenic Heat Production of Rocks”). Other radiogenic isotopes are important for age dating, such as ^{87}Rb , ^{147}Sm , and ^{187}Re (see ► “Absolute Age Determinations: Radiometric”), but the heat produced by the decay of these isotopes and other isotopes used for age dating is insignificant. Uranium, thorium, and potassium are incompatible elements and tend to be concentrated in silicic magmas. Hence, they are depleted in the mantle during crustal formation and generally concentrated in the crust in silicic rocks. Heat flow data show that their concentrations in large silicic plutons are relatively predictable from surface measurements (Roy et al. 1968), but their distributions are less predictable in metamorphic and sedimentary terrains (see ► “Lithosphere, Continental: Thermal Structure”). Measurements indicate that from as little as less than 20% to as much as 80% of heat flow may be derived from crustal radiogenic heat generation. Typical values of heat production for crustal rocks range from $<0.1\text{ }\mu\text{W m}^{-3}$ for basic igneous rocks to $>6\text{ }\mu\text{W m}^{-3}$ for radiogenic granites.

Other crustal heat sources include frictional heat from faults and heat from chemical reactions. Attempts to measure heat associated with active faults have generally failed to detect heat or produced inconclusive results. The primary chemical reaction that has been observed as a heat source is the oxidation of pyrite, but any exothermic metamorphic or weathering reaction is a potential heat source. However, friction and chemical heat sources are likely to be only local in extent and minor in terms of the total continental thermal budget.

Mechanisms of Heat Transport

In stable continental crust, the primary mechanism of heat transfer is conduction as described by Fourier’s law (Eqs. 1 and 2). In the mantle, the effects of radiative heat transfer may be significant as olivine has a significant component of radiative heat transfer above a temperature of about $500\text{ }^{\circ}\text{C}$. This radiative component may be included in Fourier’s law by substituting a temperature-dependent value of thermal conductivity that includes a correction for radiative heat transfer.

Even in stable regions, heat may be redistributed in the upper few kilometers by groundwater flow. In stable regions the geothermal gradient is seldom high enough to drive free convection (see below), and groundwater flow is driven by differences in elevation of the piezometric surface (water table). Heat transferred by the forced vertical flow of groundwater, q_{gw} , may be approximated by:

$$q_{gw} = \bar{v}c_w |dT|, \quad (5)$$

where $\bar{v}$ is the equivalent vertical velocity if the porosity were 100%, c_w is the specific heat of water, and $|dT|$ is the absolute temperature drop over the vertical extent of the water flow. Heat transfer will be in the direction of water flow and heat flow is decreased in areas of recharge and increased in areas of discharge. This type of convection is termed forced convection or advection.

If the geothermal gradient is sufficiently high, water flow may be driven by thermal buoyancy forces. The magnitude of the gradient required for the onset for thermal convection depends on the geometry of the heat source and the medium in which convection occurs (e.g., Turcotte and Schubert 2002, p. 393 et seq.). For a homogeneous porous layer of permeability km^2 and thickness b km heated uniformly from below, the minimum thermal gradient, $(\partial T/\partial z)_{\min}$, required for convection to occur is given by:

$$\left(\frac{\partial T}{\partial z}\right)_{\min} = \frac{4.2 \times 10^{-10}}{kb^2}. \quad (6)$$

This minimum gradient may not sustain convection and a higher gradient may be required for continuous convection. Convection driven by thermal buoyancy forces is termed free convection.

Heat will also be convected when there are net vertical movements within the lithosphere associated with deformation or changes in either the top or bottom boundaries of the lithosphere. In general, extensional deformation causes thinning of the lithosphere resulting in a net upward movement of the material in the lithosphere relative to its surface and a compression of the isotherms, or horizons of equal temperature within the lithosphere (Fig. 1a). In contrast, compressional deformation causes thickening of the lithosphere resulting in a net downward movement of the material in the lithosphere relative to its surface and an increase of the spacing of the isotherms within the lithosphere (Fig. 1b). For simplicity, deformation in Fig. 1 is shown to be 100% by pure shear and uniformly distributed throughout the lithosphere, a highly unlikely distribution of geological strain. As shear strength changes from brittle to ductile laterally and with depth throughout the lithosphere, the strain distribution is always much more complex: zones of simple shear, imbricated layers, and other complexities typically characterize lithospheric deformation. However, at a lithospheric scale, the net material movements and compression and extension of the geotherms illustrated in Fig. 1 are valid.

Stable continental lithosphere has a relatively low heat flow corresponding to a low geothermal gradient and strong lithosphere. These conditions are not favorable for deformation. Observations indicate that deformation commonly occurs in lithosphere that is still recovering from a previous thermal event or has experienced a preceding thermal event. This thermal event may be manifested in the form of

volcanism in which heat is advected in the lithosphere by ascending magmas. Heat transfer by magmas is conceptually similar to heat transfer by groundwater described by Eq. 5, if the specific heat of magma is substituted for the specific heat of water. Additional heat is released from a magma during solidification, and this heat is represented by the latent heat of solidification. Many analytical solutions for conductive modeling of magma intrusions may be found in Carslaw and Jaeger (1959) and other references, and these processes may also be modeled numerically. Magma generation may be initiated from below the lithosphere by the ascent of hot material to the base of the lithosphere (mantle plumes?) generating magmas by pressure-release melting and raising the temperature at the lower boundary of the lithosphere. Additionally magmas may be generated within the lithosphere by pressure-release melting and the melting of lower-melting temperature components within the lithosphere.

Once deformation is initiated additional magma generation will be initiated. The net upward movement of material during extension may trigger pressure-release melting, especially if the lithosphere has been preheated by pre-deformation magmatism. During compression, there is a net syn-deformational lowering of the geotherm. However, thickening of the crustal layer of radiogenic heat-producing elements will generally cause the geothermal gradient to return to a higher value than its initial value. This higher geotherm may result in melting of the thickened crust and crustal derived magmatism, the results of which are commonly observed in belts of compressional deformation. Thus, magmatic convection of heat is an important heat transfer mechanism that commonly accompanies heat convection by tectonic deformation.

Finally, there is heat convection associated with changes at the Earth's surface. In discussing deformation and magmatism, the effects of these processes on surface elevation were ignored. Cooling oceanic lithosphere as it ages away from oceanic ridges results in a relatively simple change in depth of the ocean floor (see ► [“Heat Flow, Seafloor: Methods and Observations”](#)). A similar, but more complex relation exists for the thermal and density structure of continental lithosphere (Lachenbruch and Morgan 1990; ► [“Isostasy, Thermal”](#)). Changes in surface elevation are generally accompanied by either erosion or sedimentation with the net result that the material in the lithosphere has a net movement either up or down relative to the surface, respectively. If the rates of erosion or sedimentation are known, a correction may be applied for these effects. If erosion creates three-dimensional topography, a terrain correction may also be applied. Not strictly a heat transfer mechanism, but changes in surface temperature associated with past climate change or changes in land use may also change surface heat flow and a correction may be applied for these perturbations.

Heat Flow, Continental,

Fig. 1 Diagrammatic examples of the effects of instantaneous pure shear deformation on lithospheric isotherms. Both diagrams have the same thermal conditions in undeformed lithosphere (no extension and no compression) calculated for a 35 km thick crust with a surface heat flow of 40 mW m^{-2} , a surface heat production of $2 \mu\text{W m}^{-3}$, and a crustal thermal conductivity of $2.5 \text{ W m}^{-1} \text{ K}^{-1}$. The crustal heat production is assumed to decay exponentially with depth with a depth parameter of 10 km, and the mantle is assumed to have a heat production of $0.084 \mu\text{W m}^{-3}$ and a temperature-dependent thermal conductivity appropriate for olivine. The base of the lithosphere is assumed to be the $1,300^\circ\text{C}$ isotherm, (a) shows the effect of thinning the lithosphere by a factor of 2 by extending the lithosphere by a factor of 2. (b) shows the effect of doubling the thickness of the lithosphere by compressing the lithosphere by a factor of 2

The duration of a thermal disturbance associated with thermal convection in the lithosphere depends primarily on the stable thickness of the lithosphere and its thermal diffusivity. There is no standard for defining this duration as temperatures relax asymptotically to their stable values, and the form of this return depends on the structure of the thermal disturbance, which may be highly variable and very complex in continental deformation with magmatism. However, a useful guideline for the duration of the thermal disturbance, τ , is:

$$\tau = \frac{L^2}{4\kappa} \quad (7)$$

where L is the stable thickness of the lithosphere and κ is its thermal diffusivity. For example, using an average thermal diffusivity of $32 \text{ km}^2 \text{ Ma}^{-1}$ and a thickness of 100 km for stable oceanic lithosphere, the calculated duration of the thermal disturbance is about 78 Ma. Oceanic crust is observed to flatten at about 70–80 Ma. For continental lithosphere, if the stable thickness of this lithosphere is 100 km, the duration

of the thermal disturbance would be about 78 Ma; if the stable thickness were 150 km, the duration would be ~175 Ma; if the thickness were 200 km, the duration would be ~310 Ma; and if the stable thickness were 250 km, the duration would be ~500 Ma. These durations are from the start of stabilization: if a deformation and magmatism event were followed by significant erosion or sedimentation, the duration of the thermal stabilization would not begin until the end of the erosion or sedimentation. However, as the effects of sedimentation and erosion are relatively minor, their measurable effects would probably be dissipated before the end of the formal disturbance duration.

Global Distribution of Continental Heat Flow

The global distribution of continental heat flow is shown in Fig. 2a. The density of data is far from uniform (Fig. 2b), but there are sufficient data that some generalizations about the heat flow distribution may be made. In general, high heat

Heat Flow, Continental, Fig. 2 (a) Distribution of continental heat flow, based on the data of Pollack et al. (1993) and subsequent updates, presented with a $10^\circ \times 10^\circ$ interpolation (Artemieva and Mooney 2001,

Fig. 3). (b) Locations of continental heat flow measurements used in constructing Fig. 2a. (From Artemieva and Mooney 2001, Fig. 4)

flow corresponds with zones of active seismicity, which in turn correlate with plate margins. Where the zones of seismicity are diffuse, such as the western US and the Himalaya,

the plate margin deformation is distributed and the zones of high heat flow are extensive. Some portions of active plate margins are associated with low heat flow, such as the

western margin of South America and the Pacific Northwest of the USA, west of the volcanic Cascade Range. These areas overlie subducting oceanic lithosphere where heat is being convected down into the mantle. Associated with these low heat flow zones is a rapid lateral transition to high heat flow in the active volcanic zones of the subduction zones. In addition, plate margins are generally associated with elevated topography, which received more precipitation than low elevations and in which heat flow is generally more variable because of redistribution of heat by forced and free groundwater convection.

The association of high and low heat flow with active plate margins is demonstrated in a plot of mean heat flow as a function of age of heat flow site (Fig. 3). Data are shown for sedimentary and metamorphic sites in Fig. 3a and igneous

sites in Fig. 3b. The data for sedimentary and metamorphic sites (Fig. 3a) show a small decrease from Cenozoic and Mesozoic to Paleozoic sites and from Paleozoic to Proterozoic sites, and a larger decrease from Proterozoic to Archean sites. This result suggests that the plate margin disturbances are relatively minor in the Phanerozoic sedimentary and metamorphic site data. In the igneous site data (Fig. 3b), however, there is a significant decrease in both the mean and standard deviation from both Cenozoic to Mesozoic and from Mesozoic to Paleozoic sites. There is almost no difference in the mean from Paleozoic to Proterozoic sites. The data are the same for Proterozoic and Archean sites as Fig. 3a. The igneous site data clearly show thermal perturbations with ages extending into Mesozoic age sites relative to older sites. This result is consistent with a continental lithospheric thickness of

Heat Flow, Continental,

Fig. 3 Continental heat flow as a function of age of data site. Widths of boxes and bars indicate age range. Heights of boxes indicate $\pm$ one standard deviation about the mean; short vertical line indicates $\pm$ one standard error about the mean. Ages of sites are grouped as C – Cenozoic, M – Mesozoic, Pz – Paleozoic, Pt – Proterozoic, and A – Archean. Numbers in parentheses are the number of 1° by 1° blocks represented in each age group. (a) shows sedimentary and metamorphic sites for Phanerozoic data. (b) shows igneous sites for Phanerozoic data. (Data re-plotted from Pollack et al. (1993))

the order of 200 km. The observation that the igneous site data show a perturbation at young ages but there is only a small signal in the sedimentary and metamorphic site data suggests that the sedimentary and metamorphic site data are dominated by sedimentary sites and that these sites are either distant from plate boundaries or high heat flow is suppressed at these sites by downward advection of heat by advection during sedimentation.

The difference between the mean heat flow at Proterozoic and Archean sites has been commented upon from previous compilations of global heat flow data (Morgan 1985) in addition to this data set (Artemieva and Mooney 2001). To explain this difference as a transient effect would require a lithosphere of the order of 500–600 km in thickness, which is probably unrealistic. However, a mean heat flow difference of 7 mW m^{-2} may be explained in terms of a difference in the contributions of the mean heat production of Proterozoic and Archean crusts to their heat flows. Assuming an average crustal thickness of 35 km, an average difference of $0.2 \text{ } \mu\text{W m}^{-3}$ would explain the difference between the mean measured heat flow at Archean and Proterozoic sites. This difference is not universally observed in all areas (Jaupart and Mareschal 1999; ► “Lithosphere, Continental: Thermal Structure”), but it is consistent with bulk observations of the differences in chemistry between the upper crust of Proterozoic and Archean terrains (McLennan et al. 2006). Archean upper crust is statistically depleted in the heat-producing elements relative to younger crust. In addition, xenolith data indicate that Archean lithosphere is statistically distinct from younger lithosphere so the upper crustal thermal observation may indicate that Archean lithosphere is statistically thermally distinct (Griffin et al. 2009).

In summary, the global distribution of continental heat flow is complex. Neglecting measurement errors (see ► “Heat Flow Determinations, Continental”), variations associated with surface temperature changes, uncorrected topographic effects, and anomalies induced by changes in surface cover, heat flow may be described as steady state or transient. At any site, near-surface heat flow may be redistributed by groundwater flow, but this is most likely at sites with high elevation and rugged topography that are likely to have experienced relatively young (Cenozoic or Mesozoic) mountain building and/or igneous activity. Transient thermal perturbations in the lithosphere associated with tectonic deformation and/or igneous activity will dissipate with time and are likely to be restricted to heat flow sites in lithosphere with Cenozoic or Mesozoic tectonic or thermal ages. To distinguish tectonic and igneous ages from sedimentary ages, the term *tectonothermal age* is commonly used to describe the age of heat flow sites. Data from sites with tectonothermal ages Paleozoic and older are generally expected to be in steady state unless erosion or sedimentation are significant.

Igneous activity always heats continental lithosphere but deformation may either raise or lower the geothermal gradient (Fig. 1). There is therefore no predictable anomaly for continental lithosphere at or near plate margins. The wide range in observed heat flow measured at young sites is in part associated with redistribution of heat by groundwater flow, but also associated with the real range in anomalies, both positive and negative, generated by deformation.

Whether the heat flow and geotherm be transient or steady state, significant variation among sites may occur associated with crustal radiogenic heat generation. Heat generation in the upper crust is very variable being generally low in mafic rocks and high in silicic rocks. Its contribution may vary from <20% to >70% of heat flow, and much of the range in heat flow represented in the standard deviations about the means of heat flow in Fig. 3 are probably associated with chemical heterogeneity in the continental crust resulting in lateral variations in the contributions of radiogenic heat production to heat flow.

Paleo-Heat Flow

The discussion above has been restricted to heat flow measured at present although there is some lag in heat flow measured at the surface as it is conducted from depth: the order of that time lag may be estimated from Eq. 7. This heat flow and associated temperatures are appropriate for most use for geophysical parameters, such as seismic wave velocities, electrical conductivities, and density calculations, but the time lag may be significant in some area where temperatures at depth in the lithosphere are changing. However, for some geological observations, including most techniques of radiometric age dating, the former temperature of a rock or mineral are preserved in a chemical or radiometric system when the rock cools as it is brought to the surface. This process may allow the temperature and sometimes the geothermal gradient of a site to be reconstructed at the time the rock was uplifted and this general topic is sometimes referred to as paleo-heat flow.

The rates of most chemical reactions increase at higher temperatures. For example, the maturation of organic material in sediments roughly follows the Arrhenius' equation, which describes the velocity of the reaction, r , as:

$$r = \lambda \exp(-E/RT_K) \quad (8)$$

where λ is the frequency factor, E is the activation energy, R is the gas constant, and T_K is temperature in Kelvin (Stegenga 1988). The combination of the frequency factor and temperature gives a time-temperature index that, together with composition of the organic matter, provides a useful predictor of hydrocarbon maturation. Temperatures in sedimentary basins

are usually estimated by the increase in coal rank of carbonaceous matter in the sediments as measured by its vitrinite reflectance (e.g., Suggate 1998), and time may be estimated by the sedimentation history of the basin. Vitrinite reflectance measures the maximum temperatures attained by the sediments, which may exceed modern temperatures.

Radiometric methods for age dating (see ► [“Absolute Age Determinations: Radiometric”](#)) do not determine rock ages but the time at which the radiometric system on which the age determination is based cools through its closure temperature, the temperature at which the age is set. Thus, radiometric ages may be used for the additional purpose of determining the thermal history of a rock, especially if some estimate of the depth at which the age was set may be determined (see below). Radiometric systems do not close at a single temperature but follow the Arrhenius’ equation; at high temperatures cooling is generally relatively rapid. Examples of approximate mineral-closure temperatures for the uranium-lead method are monazite >1,000 °C, zircon >1,000 °C, titanite 650–600 °C, apatite 500–450 °C, and rutile 450–400 °C (Flowers 2005). Examples of approximate mineral-closure temperatures for the potassium-argon system are hornblende 530 ± 40 °C, muscovite ~350 °C, and biotite 280 ± 40 °C (McDougall and Harrison 1999). Different dates from these minerals may be used to calculate rates of erosion or exhumation of terrains. However, young ages may also indicate reheating for minerals with relatively low-temperature closure temperatures.

The minerals used for some radiogenic systems have geologically very low closure temperatures. For example, the fission track technique is based on radiation damage (tracks) in different minerals caused by the spontaneous fission of ^{238}U (Garver 2008). Closure of this system is by thermal annealing of the fission tracks, which occurs at >120 °C for apatite, ~200 °C for zircon, and ~300 °C for sphene. At these low temperatures, a geothermal gradient is usually assumed and the fission track ages are commonly used to indicate recent uplift/erosion rates (uplift/erosion rate = closure temperature/[fission track age $\times$ assumed geothermal gradient]).

Finally, paleo-thermal conditions are preserved by metamorphism, and in particular in mineral systems called geothermometers. Geothermometers are typically pairs of minerals in which concentration of one element in one of the minerals has a strong temperature dependence but is essentially pressure independent; the other mineral, which must be in intimate contact with the first mineral grain, acts as a reservoir for this element and allows the first mineral to be in thermal equilibrium with the element. Geothermometers tend to equilibrate rapidly at high temperatures but re-equilibrate slowly as the temperature decreases, so if cooling and exposure at the surface is relatively rapid, the geothermometer records peak thermal conditions.

Geobarometers also exist in which the concentration of an element in the first mineral is strongly pressure (depth) dependent but insensitive to temperature. If mineral pairs representing a geothermometer and a geobarometer occur in the same outcrop, then temperature and depth may be estimated allowing calculation of the paleo-geothermal gradient and heat flow at the time of peak thermal conditions.

Studies of paleo-thermal gradients from metamorphic terrains suggest that, on average, geothermal gradients were higher than modern average geothermal gradients. However, although global heat flow was almost certainly higher in the past than at present (see ► [“Energy Budget of the Earth”](#)), these observations do not demonstrate that conclusion for the following reasons: (1) only peak or near-peak thermal conditions are preserved resulting in an overestimation of average continental heat flow; (2) peak preserved geothermal gradients are no higher than geothermal gradients measured today – modern geothermal gradients are buffered in the uppermost crust by the water boiling point curve and at greater depths by the crust solidus, and the same conditions would have applied in the earliest Earth preserved in the continental crust; and (3) if there were zones of low temperature/high pressure metamorphism (blueschist) in the Archean/Early Proterozoic, they are unlikely to be preserved because a geotherm required to maintain these metamorphic conditions requires active subduction. With the cessation of subduction, the geotherm would relax to a warmer geotherm, and blueschist metamorphism is likely to be overprinted. Similarly, low temperatures would not be recorded by geothermometers as the lithospheric temperatures increase.

Summary

Continental heat flow is a complex, but fundamental parameter that, together with oceanic heat flow, constrains the energy budget of the Earth heat engine. It is particularly complex because continents are complex and heterogeneous. It has components from beneath the lithosphere and radiogenic heat production within the lithosphere. Heat is advected into and within the lithosphere by magmatic activity, and heat is redistributed by lithospheric deformation associated with plate tectonics and at relatively shallow depths by groundwater flow. Changes in surface conditions also modify heat flow in the shallow crust. The time constant of thermal relaxation of continental lithosphere is of the order of 300 Ma for stable lithosphere 200 km in thickness. Typically heat flow data from igneous sites of Cenozoic and Early Mesozoic ages reflect transient thermal conditions; data from sites of older ages do not. However, continental heat flow remains very variable even at Precambrian sites because of lateral variability in crustal radiogenic heat production.

Definition

Conductive heat flux	The rate of heat transfer through a substance per unit area. The conductive heat flux, commonly defined in one dimension, is the product of the thermal gradient and thermal conductivity, with SI units of W m^{-2} . Heat flux is referred to in historical and some current oceanographic literature as “heat flow,” but in precise physical terms, heat flux equals heat flow density.
Advective heat flux	The rate of heat transfer per unit area as a consequence of material motion. The advective heat flux is commonly defined as the product of the temperature, heat capacity, and material velocity, with SI units of W m^{-2} .
Thermal conductivity	The constant of proportionality that relates the thermal gradient to the conductive heat flux, indicating the ability of a medium to transfer heat by conduction. SI units are in $\text{W m}^{-1} \text{K}^{-1}$.
Hydrothermal circulation	Large-scale pore-fluid convection driven by geothermal buoyancy, with flow being strongly influenced by permeability structure of the host formation.

History of Observations

Pioneering measurements of temperature below the seafloor (e.g., Petterson 1949; Revelle and Maxwell 1952; Bullard 1954) were made to compare the thermal state of the ocean crust with that of continents and thus to improve the knowledge of the present-day heat loss from the Earth. The early data demonstrated that gravity-driven probes and corers that penetrated just a few meters into seafloor sediments could provide meaningful measurements of geothermal gradients, and they thus established the foundation for the marine heat flow discipline. Methods for measuring the subseafloor

thermal gradient and thermal conductivity improved in subsequent years, the number and geographic distribution of determinations increased, and patterns of seafloor heat flux were gradually revealed. Initially, the average seafloor heat flux appeared to be similar to that through continents, despite the contribution of radiogenic heat produced by the continental crust that was not present in the ocean crust. Heat-flux values over mid-ocean ridges were found to be significantly higher than in the flanking basins, and locally values were often inexplicably scattered (Von Herzen and Uyeda 1963; Lee and Uyeda 1965). Higher heat flux at mid-ocean ridges was consistent with emerging ideas about seafloor spreading, although the values measured were lower than expected from early theoretical models for the formation of ocean lithosphere. For nearly two decades, regionally low and scattered seafloor heat-flux values remained unexplained, although there was early speculation about the possibility that fluids flowing through the seafloor might influence heat loss from the ocean crust (Elder 1965; Langseth et al. 1966).

By the 1970s, heat flow surveys with more closely spaced measurements, made in the context of local sediment thickness and igneous crustal structure, helped to confirm the hypothesis that hydrothermal circulation in the igneous crust caused both the scatter and the lower-than-expected values in young areas (Lister 1972). Further improvements to instrumentation and observational strategies, in particular the development of probes that could be used with great efficiency for multiple measurements during a single instrument lowering, and the practice of making measurements in the context of geologic structure, led to the use of heat flow as a tool to study the process of hydrothermal circulation itself (Williams et al. 1974). With this new knowledge, it became possible to decipher the local and regional variability of measurements in a way that could lead to a better quantification of deep-seated heat flux, the goal of the original marine heat flow studies, and to understand the hydrologic processes behind the perturbations. This led to studies across a range of spatial and temporal scales using marine heat flow and complementary measurements to solve numerous problems. A summary of the suite of tools currently in use for these studies is provided in the next section, along with a brief description of how heat-flux determinations are made. This is followed by a few examples of data from specific studies that illustrate how data are used, and a summary of some of the major conclusions that have been made through such studies.

Methods

Shallow Measurements in Marine Sediments

Heat flux through the seafloor is often determined using the combination of temperatures measured with a series of

sensors mounted on the outside of gravity-driven corers (Fig. 1a) and thermal conductivities measured on the recovered sediment cores. Depths of penetration in excess of 10 m can be achieved in soft sediment, providing a valuable check on potential perturbations from bottom-water temperature variations (discussed below), although accuracy is often limited by physical disturbances caused by the coring process, by changes in the physical properties of the recovered material, and by the imperfect depth registration between the cores and the intervals between the temperature sensors (Fisher et al. 2002). Probes devoted exclusively to heat-flux measurements are typically limited to lengths of a few meters, but they have several distinct advantages. They allow thermal conductivity to be measured under in situ conditions and at depths that are co-registered with the sensors used to determine the gradient, and they allow transects of many measurements to be made efficiently during a single instrument lowering. A typical heat-flow probe (Fig. 1b) employs a heavy strength member that resists bending during repeated sediment penetration and withdrawal; this strength member supports a small-diameter, rapidly responding tube containing thermistor sensors and a linear heater element. Tools used with submersibles are shorter and use a thin sensor tube, but not a strength member (Fig. 1c). In situ temperatures are estimated by extrapolating transient decays following probe penetration, and conductivities are determined from the rate of change of temperature following steady or impulsive activation of a heater. A typical data record is shown in Fig. 2, as are the resulting determinations of temperature and thermal conductivity. Heat flux is determined as the slope of a linear regression fit of temperature vs. cumulative thermal resistance, R :

$$R = \Sigma [\Delta z / \lambda(z)],$$

where λ is thermal conductivity measured at a series of depths, z , and Δz is the depth interval assumed to be represented by each measurement. This is equivalent to multiplying the thermal gradient by the thermal conductivity if the latter does not vary with depth. Errors associated with possible bottom-water temperature variations (discussed later) are evaluated by examining systematic deviations from linearity as a function of the number of thermistors included in the fit, working progressively up towards the shallowest measurement point. If there is systematic curvature in a plot of T versus R , it may indicate rapid, vertical fluid flow through sediments with associated advective heat transport. This has been noted in some hydrothermally active areas (e.g., Stein and Fisher 2001; Wheat et al. 2004), but is otherwise rare. Complete descriptions of instruments and discussions of data

Heat Flow, Seafloor: Methods and Observations, Fig. 1 Sensors and probes for measuring temperatures and thermal conductivity in marine sediments, including (a) outrigger temperature sensors mounted to the outside of a sediment corer (core barrel is 12 cm diameter), (b) a multipenetration heat-flow probe for measuring sediment temperatures

and thermal conductivities (total length is 6 m; photo courtesy of H. Villinger), (c) a 60-cm-long probe for measuring sediment heat flux with manned submersibles and remotely operated vehicles, and (d) a high-strength probe that extends below a drill bit for bottom-hole temperature measurements (length is 1.2 m, tip diameter 1 cm)

reduction methods can be found in Lister (1979), Hyndman et al. (1979), Davis (1988), Wright and Loudon (1989), Villinger and Davis (1987), and Stein and Fisher (2001).

Deep Borehole Measurements

Where observations are needed in hard formations or at depths greater than can be penetrated with a gravity-driven device, drilling is required. For research objectives, this has been done primarily through the Deep Sea Drilling Project and the successive Ocean Drilling, Integrated Ocean Drilling, and International Ocean Discovery Programs. In relatively

unconsolidated sediments (typically the uppermost 50–100 m below the seafloor), hydraulically driven piston corers are deployed from the bottom of the drill string, and temperatures are measured at the tip of the core barrel (Horai and Von Herzen 1985; see Heesemann et al. 2006). At greater depths below the seafloor, high-strength probes can be pushed in with the weight of the drill string sufficiently far below the bottom of the hole (c. 1 m) to gain a measurement unperturbed by drilling (Uyeda and Horai 1980; Davis et al. 1997a) (Fig. 1d). Deeper than a few hundred meters in sediment, or at any level in crystalline rock, direct formation

Heat Flow, Seafloor: Methods and Observations,

Fig. 2 Typical data (upper panel) collected with a marine heat probe like that shown in Fig. 1b. Natural sediment temperatures are determined by extrapolating the transients following probe insertion, and thermal conductivities are determined from the rates of decay following the metered pulse of heat. In this example, high conductivities associated with two turbididic sand layers are present

measurements are not feasible; instead, temperature logs in the open hole or long-term borehole measurements are required to discriminate the natural formation thermal state from the commonly large and long-lived perturbations from drilling and subsequent fluid flow into or out of the hole. The most reliable method for determining the natural thermal state of crustal rocks has been to seal holes and install thermistor strings for long-term monitoring (Davis et al. 1992) (Fig. 3).

In a few cases, borehole and seafloor probe measurements have been made in close proximity (Fig. 4; Davis et al. 1999, 2003). Comparisons like these provide verification that

perturbations from processes like bottom-water temperature variations (discussed below), sedimentation, mass wasting, or pore-fluid advection are not present, and that shallow probe measurements give accurate values of the local geothermal heat flux.

Estimating Heat Flux From the Depth Limit of Gas Hydrate Stability

Sediments in some areas of the oceans contain sufficient quantities of gas to host subseafloor, solid gas hydrates.

Heat Flow, Seafloor: Methods and Observations, Fig. 3

Two records from a 10-thermistor cable suspended in a borehole that penetrates a c. 600-m-thick sediment layer and into the underlying uppermost igneous oceanic crust. The longer recovery time at the deeper level reflects the cooling effects of the large volume of water that invaded the uncased and permeable igneous section during the 5 days between the time of drilling and when the hole was sealed and instrumented

Heat Flow, Seafloor: Methods and Observations, Fig. 4

Comparison of co-located seafloor probe and borehole heat-flux observations. Variations in probe measurements along the transect adjacent to the borehole site illustrate how carefully such comparisons must be done. (Data from Davis et al. 2003)

Beyond being interesting in their own right, gas hydrates offer a means for estimating heat flux. The stability of gas hydrate is dependent on temperature and pressure, and the stability limit is commonly seen as a seismic reflector that marks the

boundary between sediment above containing gas hydrate, and sediment below containing free gas. Where heat flux is relatively constant, this reflector follows small local variations in seafloor depth and is referred to as a bottom

Heat Flow, Seafloor: Methods and Observations, Fig. 5 A methane-hydrate bottom simulating reflector in the Cascadia subduction zone accretionary prism offshore western Canada. In this example, coring, logging, and long-term temperature monitoring along a thermistor array in a co-located Integrated Ocean Drilling Program borehole

have allowed precise measurements of the depth and temperature at the BSR and of the thermal conductivity of the overlying sediments, and thus an accurate determination of the heat flux at the location of the borehole (53 mW m^{-2}) and elsewhere along this and nearby seismic profiles

simulating reflector (BSR; Fig. 5). The strongest factor governing the subseafloor depth to the limit of hydrate stability is temperature, and thus the BSR depth can be used to estimate the local heat flux. The methodology, introduced by Yamano et al. (1982) and reviewed in detail by Villinger et al. (2010), is especially valuable where bottom-water temperature variability is too large to permit accurate heat-flux determinations with shallow probes, where sediments are too hard to allow probe penetration, to interpolate between or extrapolate from sparse direct measurements, or to gain information where standard measurements are simply not available.

Several factors must be considered for accurate application of this method, including the temperatures at the seafloor and at the BSR hydrate stability boundary. The latter can be defined via an estimation of pressure at the boundary and the equation of state for the gas/gas-hydrate/water system or from an empirical relationship (e.g., Dickens and Qinby-Hunt 1997). It is normal to assume a seawater/methane system, although the presence of higher hydrocarbons and of porewater having higher or lower salinity than seawater both have effects (e.g., Andreassen et al. 2000; Ruppel et al. 2005). Next, the depth to the BSR must be estimated. This requires a conversion between two-way travel time (from seismic reflection data) and sediment thickness from the seafloor to the BSR, using velocities that can be estimated from seismic refraction, wide-angle reflection, or drilling data. If both the depth and temperature can be defined from drilling (e.g., Fig. 5), then much uncertainty can be eliminated and the resulting estimates of thermal gradient derived from BSRs can be extended regionally with greater confidence. To determine the heat flux, the cumulative thermal resistance from the seafloor to the depth of the BSR is required. This is commonly calculated

using the average of thermal conductivity values measured in core samples, or estimated using porosity or seismic velocity data.

Example Studies

Heat Flow Signals from Hydrothermal Circulation

Hydrothermal circulation can both extract and redistribute lithospheric heat, making it difficult to determine the heat flux from deep in the lithosphere, although the pattern of redistribution can provide a valuable tracer of fluid flow. This has been the focus of a large number of studies (see review in Fisher and Harris 2010). Two instructive examples of the influence of hydrothermal circulation are shown in Fig. 6, where closely spaced measurements were made along transects striking perpendicular to basement structure. The first (Fig. 6a) crosses a sediment-covered area adjacent to a region of outcropping igneous crust, close to a spreading ridge axis (where measurements with conventional probes are impossible). Local variations correlated with sediment thickness variations are present, as is a systematic variation over a larger scale, with heat flux increasing with distance from the area of basement outcrop, opposite to the expected trend of decreasing heat flux with increasing seafloor age. Temperatures estimated at the top of the igneous section also increase systematically with distance from the ridge. Both trends suggest that crustal heat is laterally advected from the crust and lost to ventilated hydrothermal circulation at neighboring locations where sediment cover is absent or discontinuous. Away from areas of igneous outcrop, the hydrothermal system becomes increasingly sealed by sediments, and the measured seafloor heat flux values approach that expected from models of lithospheric cooling. Examples elsewhere suggest that the

Heat Flow, Seafloor: Methods and Observations, Fig. 6 (continued)

Heat Flow, Seafloor: Methods and Observations, Fig. 6 Transects of heat flux colocated along seismic reflection profiles on the flanks of the Juan de Fuca Ridge (a) striking away from a region of extensive basement near the left end of this profile, and the Costa Rica Rift (b) where an extensive sediment cover is present. Both show the effects of hydrothermal circulation on conductive seafloor heat flux and the crustal thermal regime. Heat flux estimated on the basis of the local lithosphere age (see text) is shown as the dashed line. Temperatures below the

seafloor extrapolated from seafloor probe measurements and observed in boreholes (Ocean Drilling Program site numbers given) are shown near the top of the igneous crust at intervals of 10 °C. The schematic diagram in (c) shows the influence of sediment burial on hydrothermal circulation and advective heat loss within and from the igneous crust, with panels 1–4 reflecting a general age progression from young, unsedimented seafloor to old, sediment-buried crust with permeability ultimately diminished by hydrothermal alteration

effects of advective heat loss from the upper igneous crust may be felt laterally as far as 50–100 km (e.g., Fisher et al. 2003; Fisher and Wheat 2010) and that advective heat transport is most effective in directions parallel to structural strike.

The second example (Fig. 6b) is in an area where sediment cover is continuous over a broad region spanning several tens of km. Locally, heat flux varies inversely with sediment thickness, much as in the case of local variations seen in Fig. 6a. Such variations are common in areas of young seafloor, but can occur across relatively old seafloor as well (Embley et al. 1983; Von Herzen 2004; Fisher and Von Herzen 2005). They are the consequence of thermally efficient, local convection in permeable igneous rocks beneath low-permeability sediment cover. If the permeability of the igneous “basement” formation is high, vigorous convective flow maintains nearly constant temperatures at the sediment/basement interface despite variations in the thermal resistance of the overlying sediment layer. In this instance, the average seafloor heat flux is close to that expected from the underlying lithosphere, suggesting that the circulation in the upper igneous crust may redistribute heat locally, but is not extracting heat advectively.

Ever since the early work of Lister (1972), the mere presence of local variability has been used as a diagnostic indicator of hydrothermal circulation in both young and old areas (e.g., Fig. 6c), but with widely spaced observations, neither of the signals exemplified in Fig. 6a, b could be resolved coherently; values were simply scattered and averages were often low. When systematic, detailed transects of observations began to be completed in context of co-located seismic data, the vigor of the convection could be inferred quantitatively from the nonconductive thermal regime (Fisher and Becker 1995; Davis et al. 1997b), and the amount of heat lost from the

crust by fluid advection could be estimated with growing confidence (e.g., Anderson and Skilbeck 1980; Stein and Stein 1994; Harris and Chapman 2004).

Two major lessons are learned from detailed observations like these for drawing conclusions about deep-seated heat flux. First, to ensure that observations do not suffer from the bias caused by advective heat extraction, it must be demonstrated that there are no exposures of permeable rock at faults or volcanic edifices within distances of at least several tens to 100 km or more. Second, large numbers of closely spaced observations must be made, ideally co-located with seismic reflection data, so that the local variability can be understood and meaningfully averaged, and the locally relevant lateral transport scale can be assessed (e.g., Sclater et al. 1976; Davis et al. 1999; Villinger et al. 2002). To develop a regional understanding, these transects should be created as part of a spatial grid, extending both across and along the structural strike of the underlying crust, to help resolve the possibility of advective heat loss from the crust in any direction.

Interest in hydrothermal processes and their influences on water-rock-energy-chemical-biological interactions continues to grow. Estimates for the temperatures of circulation, the chemistry of the fluids, the volumetric rates of exchange between the crust and the ocean, and the consequent effects on crustal alteration and ocean chemistry have become reasonably well understood (e.g., Mottl and Wheat 1994; Elderfield and Schultz 1996; Fisher and Wheat 2010). Ongoing topics of research include the distribution of crustal permeability (e.g., Becker et al. 2013; Fisher et al. 2014), the percentage of rock affected by hydrothermal alteration (e.g., Coggon et al. 2014), and the influence of thermal and chemical conditions on chemosynthetic microbial populations (e.g., Orcutt et al. 2015).

Dependence of Heat Flux on Age and the Global Average

With the potentially large influence of hydrothermal circulation in mind, it is clear that a simple compilation of heat-flux data will provide a biased view of global heat loss. Except in old ocean basins (and in locations that are tens to hundreds of km from the nearest areas of exposed basement), values are likely to be highly variable and low relative to the heat loss expected from the underlying lithosphere. But by taking only those measurements that are sufficiently far from known permeable igneous outcrops, and sufficiently numerous to provide a reliable local average, a subset of data can be gathered that provides a reliable determination of deep-seated heat flux. When considered in context of lithospheric age, the results have been found to be consistent with both the characteristics of age-dependent seafloor subsidence and with simple lithospheric cooling theory (see entry on “Oceanic Lithosphere: Thermal Structure”). In young areas, heat flux is found to decline linearly with the inverse square root of age, following the simple relationship $Q = C t^{-1/2}$ (where Q is heat flux in mW m^{-2} , t is age in Ma, and C is a constant estimated between 475 and 510; see Harris and Chapman 2004). High-quality observations in older regions (>100 Ma) show heat flux to be generally uniform, in the range of $45\text{--}50 \text{ mW m}^{-2}$ (Lister et al. 1990; Hasterok et al. 2011), suggesting that the thermal structure of the lithosphere may become stabilized in

a state regulated either by the convectively supplied heat flux from the underlying asthenosphere or by the combination of a compositionally established lithospheric thickness and the relatively uniform temperature of the vigorously convecting asthenosphere.

With the relationship between heat flux and age thus defined, the problems of the unknown bias and large local variability in young areas and of the sparse distribution of measurements in large portions of the oceans can be overcome. This, together with seafloor ages defined by magnetic anomalies, allows a robust determination of the heat flux throughout the oceans (Fig. 7). Furthermore, with a seafloor area/age relationship (e.g., Parsons 1982; Wei and Sandwell 2006), the total heat flow through the oceans can be estimated. Several such estimates have been made (e.g., Williams and Von Herzen 1974; Sclater et al. 1980; Jaupart et al. 2007; Davies and Davies 2010), and all fall in a relatively narrow range centered around 32 TW (with contributions from marginal seas and hot-spot swells included). This yields an average total seafloor flux of roughly 107 mW m^{-2} , a number that has little physical significance but is considerably greater than that estimated in the early days of marine heat flow, and greater than the average though continents (c. 67 mW m^{-2}), particularly when the latter is adjusted for the contribution of continental crustal radiogenic heat (c. 33 mW m^{-2}).

Heat Flow, Seafloor: Methods and Observations, Fig. 7 Total heat flux through the oceans and continents, with factors such as advective hydrothermal heat loss through the seafloor accounted for. Color scaling is given in mW m^{-2} . The distribution of constraining observations is highly variable and sparse in many regions; values shown are based

primarily on age in the oceans (in the manner described in the text), and on age and geologic province in continental regions (from Davies and Davies 2010). The pattern of the regional variations demonstrates the important role of lithospheric creation at seafloor spreading centers in liberating Earth's internal heat

Conversely, with the total heat flow thus constrained, the heat lost advectively by hydrothermal circulation flowing through the seafloor (Fig. 6c panels 1 and 2) can be estimated from the difference between the total as determined above and the age-binned average of unfiltered observations. Such estimates of this “heat deficit” fall in the neighborhood of 10 TW (Stein and Stein 1994; Harris and Chapman 2004), meaning that over 20% of Earth’s total heat loss (32 and 14 TW from the oceans and continents, respectively) occurs by this mechanism. Most of the oceanic hydrothermal heat loss occurs from seafloor less than 8–10 Ma in age, and the deficit disappears (on average) by ~65 Ma. The actual age at which advective loss becomes insignificant is locally variable, depending primarily on the continuity of accumulating sediments that bury the igneous crust (Anderson and Skilbeck 1980; Harris and Chapman 2004).

The Signature of Subduction

Marine heat flow is used extensively to constrain deep thermal structure in studies of continental margins, marginal basins, and subduction zones. Particular attention has been given to the last in an effort to help define associated seismic hazards. A transect crossing the forearc prism of the Cascadia subduction zone illustrates one such application (Fig. 8). This transect begins with standard gravity-driven probe

measurements over the incoming plate and outermost accretionary prism, where bottom-water temperature variability is small. At the inner prism and on the continental shelf, where seafloor is shallower than 1500–2000 m, other measurement techniques are used, including borehole measurements and estimates made using the depth to a BSR which marks the limit of methane-hydrate stability. Observations like these allow the underlying thermal structure to be inferred, providing critical constraints on dehydration reactions, the rheology and frictional properties of the sediments and rocks, and the potential for seismogenic slip along the subduction thrust interface. In this example, the seafloor heat flux is variable locally, but regional values and trends are consistent with the expected thermal state created by the subduction of the oceanic plate and accretion of the thick sedimentary section.

More recently documented cases summarized by Harris et al. (2017) include the Middle America Trench, where the thermal state of the incoming Cocos plate is influenced by regionally varying hydrothermal heat loss. These variations correlate with differences in seismic processes occurring in the subduction zone itself (Newman et al. 2002; Fisher et al. 2003; Harris et al. 2010). One part of the plate is extensively cooled by hydrothermal circulation before the Cocos Plate is subducted, and earthquakes observed within the subduction wedge in this area are relatively deep (>20 km).

Heat Flow, Seafloor: Methods and Observations, Fig. 8 Structural and heat-flux transect across the Cascadia subduction forearc, with temperatures estimated from a numerical model for underthrusting and

sediment thickening, constrained by the heat-flux data (following compilation of Hyndman and Wang 1993)

Earthquakes tend to be shallower (<20 km) along an adjacent segment of the subduction zone, where there is no evidence for regional advective heat extraction from the oceanic plate. One explanation for the different earthquake depths is that cooling of part of the Cocos Plate slows dewatering and deepens the transition of smectite to illite in subducting sediments (Spinelli and Saffer 2004; Lauer et al. 2017). The delay in heating associated with hydrothermal circulation in the crust prior to subduction causes a landward shift of the locked region where earthquakes are most likely to occur.

Bottom-Water Temperature Perturbations

Seafloor heat-flux measurements rely on the assumption that both long- and short-term bottom-water temperature (BWT) variations are small. This is often considered a good assumption because the volume of ocean bottom water is large and the temperature of the source in polar regions is regulated by the formation of sea ice. However, many early heat-flux measurements were made with 2–3 subsurface temperatures extending to depths of only a few meters, and it was difficult to identify nonlinearities that might indicate a recent change

in bottom water temperature. Good checks on the stability of BWTs were not possible until temperature observations began to be made in deep-sea boreholes and long records of bottom-water temperature were acquired (Hyndman 1984; Davis et al. 2003). An ideal suite of observations that would allow errors associated with bottom-water temperature variations to be quantified throughout the world's oceans – one that is broadly distributed both geographically and with ocean depth – does not yet exist, but the available data show that gradients measured a few meters below the seafloor do permit accurate determinations of heat flux in large areas of the oceans, generally where depths are greater than ~ 2000 m. One such check is illustrated in Fig. 4, where closely co-located seafloor probe and borehole observations are compared. Significant bottom-water temperature variations are ruled out by the linearity of the plots of temperature versus cumulative thermal resistance and by the agreement between the shallow probe and deep borehole determinations. This illustration also shows the importance of precise co-location when doing such a comparison, given the scale and magnitude of the local spatial variability of heat flux as defined by neighboring probe measurements.

Heat Flow, Seafloor: Methods and Observations, Fig. 9 Bottom-water temperature variations observed at 5000 m depth in the western Atlantic Ocean (a) and 2600 m depth in the Pacific Ocean (c), and perturbations of the geothermal gradient as a function of depth (b and

d) stemming from the variations, calculated at an evenly distributed suite of times during the temperature time series (data from Davis et al. 2003). These calculations show how data collected with short probes may be subject to significant errors due to changes in bottom water temperature

A more direct approach uses observations of bottom water fluctuations themselves. Perturbations attenuate with depth over a scale that is determined by the period and thermal diffusivity of the sediment, following the relationship $T(z) = T(0) \exp(-z/2\kappa\Gamma)^{1/2}$, where $T(0)$ is the fluctuation amplitude, κ is the thermal diffusivity, typically $= 4 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$, and Γ is the period of fluctuation. The effect on the thermal gradient is illustrated in Fig. 9 for two specific examples. The first, from a 5000-m-deep site in the western Atlantic, shows that oceanographic perturbations fall below the threshold of significance for heat-flux determinations by a depth of 2–3 m below the seafloor (Fig. 9a, b). The second, from a 2600-m-deep site in the eastern Pacific, shows smaller variability; there, significant perturbations would propagate less than 1 m below the seafloor (Fig. 9c, d). Generally speaking, the greatest stability is found in regions of great water depth and great distances from bottom-water sources in polar regions. A better definition of this as a potential source of error in heat-flux measurements is expected to emerge as the number of long-duration oceanographic monitoring experiments increases. In areas where bottom water temperature variations are likely to be problematic, local monitoring can allow local heat-flux measurements to be corrected (e.g., Neumann et al. 2017).

Summary

Heat flux, the product of the thermal gradient and thermal conductivity, can be measured with high accuracy in most deep-ocean settings with gravity-driven probes that penetrate a few meters into seafloor sediment. Meaningful values for deep-seated heat flux require a full understanding of the potentially large influence of hydrothermal circulation in the underlying permeable igneous rocks of the upper oceanic crust, however. This is best gained through closely spaced transects of heat-flux measurements co-located with seismic reflection profiles that show the structure of the underlying volcanic rocks. Such studies provide valuable constraints on the flow of water within the oceanic crust, the exchange of water, heat, and solutes between the crust and the oceans, the formation of hydrothermal mineral deposits, the accumulation of gas hydrates, and the development and maintenance of a sub-seafloor microbial biosphere. Where the effects of hydrothermal circulation can be accounted for or are known to be insignificant, deep-seated flux can be reliably determined and used to estimate the thermal history of sedimentary basins and the thermal regime of seismogenic fault zones; to understand seafloor spreading, the aging of oceanic lithosphere, and the origin of mid-plate swells; and to define the global heat budget which is dominated by heat loss through the seafloor.

Height Systems, Vertical Datums and Their Unification

Michael G. Sideris

Department of Geomatics Engineering, University of Calgary, Calgary, AB, Canada

Definition

Height or *elevation* of a point P on the Earth's surface is the distance from P to a reference surface of zero height, measured along a precisely defined path.

Different *Height Systems* result from the choice of the reference surface and the path from P to that surface.

Vertical Datum is a surface of zero height, typically defined as the equipotential (level) surface of the Earth's gravity field that passes through an accessible *fundamental point*.

Vertical Datum Unification is the process of connecting vertical datums to each other, or to one main datum, by determining the offsets between existing vertical datums.

Note: the above definitions refer primarily to *physically meaningful heights*, i.e., to heights that express, and depend on, differences of the Earth's gravity potential.

Introduction

Height differences and absolute heights can typically be obtained by spirit levelling (see ► “[Geodesy, Ground Positioning, and Levelling](#)”) or by combining Global Navigation Satellite Systems (GNSS) positioning methods with a model of the geoid (see ► “[Geoid Determination, Theory and Principles](#)”). Their accurate determination is essential for many engineering and environmental applications of high

societal impact, both globally and regionally. In such applications, height differences need to represent potential differences between points and not just geometric differences as those obtained from, e.g., GNSS. Furthermore, these heights need to refer to the same zero-height reference surface or *vertical datum*, and hence the need for determining the offsets between existing vertical datums, i.e., vertical datum unification. These offsets can be estimated if the geodetic, physical and geoid heights (from GNSS, spirit leveling and gravity information, respectively) are known for the fundamental and/or other points in each vertical datum. Besides a geoid model obtained from the solution of the geodetic Boundary Value Problem (BVP), height data from GNSS-surveyed levelling benchmarks on land, GNSS-surveyed tide gauge stations along coasts, and a mean dynamic topography model at sea can be used in the computations. In this entry, therefore, we present the most common height systems, the theoretical definition and practical realization of a vertical datum, and the unification of existing vertical datums, geared in particular towards the realization of the International Height Reference System (Ihde et al. 2017; Sánchez and Sideris 2017).

Obtaining height differences by traditional spirit leveling supplemented by gravity observations between benchmarks is a very labor-intensive, time-consuming, terrain- and weather-dependent, and costly undertaking. Height modernization in many countries now relies on height differences by GNSS positioning methods and the geoid (Véronneau and Huang 2016; see Fig. 1). Although in this way the limitations of spirit leveling are avoided, the resulting heights are *ellipsoidal* or *geometric heights*, h , above the surface of a reference ellipsoid while the former method provides *orthometric heights*, H , above the surface of the geoid (length of line PQ_0 and curved line PP_0 in Fig. 2, respectively). Only the orthometric heights have a physical meaning as they represent potential differences between benchmarks (see section “[Height Systems](#)” below), which are indispensable for environmental monitoring applications (e.g., sea level rise, coastal inundation, floods) and water resources applications (e.g., dams, drainage, irrigation). As it can be seen in Figs. 1 and 2, it is possible to convert GNSS-derived ellipsoidal heights to orthometric heights, through the use of geoid undulations, N , by use of the simple expression $H = h - N$ (see also Eq. 4 below). National height modernization efforts rely of this simple equation and allows users to obtain orthometric heights at any point by simply using a GNSS receiver together with the national geoid model.

Height Systems

We have already mentioned that the reference surface, i.e., the surface of zero height in a particular height system, is called

Height Systems, Vertical Datums and Their Unification,

Fig. 1 Traditional and modern way of height determination (h , H and N denote ellipsoidal heights, orthometric heights and geoid undulations, respectively)

Height Systems, Vertical Datums and Their Unification,

Fig. 2 Geometry between ellipsoidal ($h = PQ_0$), orthometric ($H = PP_0$), and normal heights ($H^* = QQ_0$), geoid undulations ($N = P_0Q_0$), and height anomalies ($\zeta = PQ$)

vertical datum, and heights are measured along straight or curved lines above it. For example, geodetic (or ellipsoidal) heights h derived from GNSS observations are “measured” along the normal to the surface of an ellipsoid, which is the datum in the *geodetic height system*. Because geodetic heights do not represent potential differences and therefore cannot be used for applications like the ones mentioned in the introduction, other, physically meaningful, height systems are in use. They are based on the following equation that relates differentially height to gravity g and gravity potential W (Hofmann-Wellenhof and Moritz 2006):

$$dh = -\frac{dW}{g} \quad (1)$$

Using h to denote a generic height, $\tilde{g}$ to denote the average gravity from the reference surface to a point P on the Earth's surface along the line perpendicular to the gravity

equipotential surfaces (plumb line), and integrating along the plumb line we obtain

$$\begin{aligned} C_P = W_0 - W_P &= -\int_0^{h_P} dW = \int_0^{h_P} g dh = h_P \frac{1}{h_P} \int_0^{h_P} g dh \\ &= h_P \tilde{g}_P \end{aligned} \quad (2)$$

$$h_P = \frac{C_P}{\tilde{g}_P}, \quad \tilde{g}_P = \frac{1}{h_P} \int_0^{h_P} g dh \quad (3)$$

C_P in Eq. (2) is the difference between the gravity potential W_0 of the datum (typically, the geoid) and the gravity potential W_P of any point P on the Earth's surface, called *geopotential number*. The unit for C is the geopotential unit, g.p.u., where 1 g.p.u. = 1000 Gal m. Numerically, geopotential numbers in g.p.u. are almost equal to heights in meters since, using an average g -value of 981 Gal, $C_P = \tilde{g}_P h_P \approx 0.981 h_P$.

Three different height systems can be defined based on the choice of $\tilde{g}$ in Eq. (3):

- The *dynamic height system* ($h = H^d$ when $\tilde{g} = \gamma_{45}$)
- The *orthometric height system* ($h = H$ when $\tilde{g} = \bar{g}$)
- The *normal height system* ($h = H^*$ when $\tilde{g} = \bar{\gamma}$)

where γ is the gravity of the reference ellipsoid, γ_{45} is the value of γ at geodetic latitude $\phi = 45^\circ$, and the overbar denotes average gravity along the corresponding plumb line. In Fig. 1 in Sideris, ▶ “[Geoid Determination, Theory and Principles](#)”, h , H , and H^* are the lengths of the lines PQ_0 , PP_0 , and QQ_0 , respectively. Usually, the curvature of the plumb lines and the

small deflection angles are ignored, resulting in a simpler figure, such as Fig. 2 above, which illustrates the relationship between geodetic, orthometric, and normal heights, as well as geoid undulations N and height anomalies ζ :

$$h = H + N = H^* + \zeta \quad (4)$$

N and ζ – and the corresponding surfaces of the geoid and telluroid/quasi-geoid – are obtained as the solutions to the Stokes and Molodensky geodetic BVPs, respectively; the relevant theory and methodology are given in this volume in ► “Geoid Determination, Theory and Principles” and ► “Geoid Determination, Computational Methods”. Furthermore, using Eq. (4) above and Eq. (23) in Sideris, ► “Geoid Determination, Theory and Principles”, they can be related by the following expression through the Bouguer anomaly Δg_B :

$$N - \zeta = H^* - H = \frac{\bar{g} - \bar{\gamma}}{\bar{\gamma}} H \approx \frac{\Delta g_B}{\bar{\gamma}} H \quad (5)$$

It should be noted that Fig. 2 does not depict dynamic heights H^d as they have no geometrical representation; they are basically potential differences given in units of length. Nevertheless, they are very important in applications that require direct knowledge of potential differences; as an example, dynamic heights are used in the International Great Lakes Datum of 1985 (IGLD85) for safe navigation in the Great Lakes of North America. A very good introduction to these height systems and vertical datums is given in Jekeli (2000), and a detailed treatment can be found in Sansò et al. (2019).

Although physical heights are not directly measurable, they could be derived from height differences Δn_{AB} observed by spirit leveling between two points A and B (see Fig. 1), by applying a gravity-dependent *height correction* hc_{AB} :

$$\begin{aligned} \Delta h_{AB} &= h_B - h_A = \frac{C_B - C_A}{\bar{g}} = \frac{1}{\bar{g}} \int_A^B g dn = \frac{1}{\bar{g}} \int_A^B (\tilde{g} + g - \tilde{g}) dn \\ &= \int_A^B dn + \int_A^B \frac{g - \tilde{g}}{\bar{g}} dn = \Delta n_{AB} + hc_{AB}, \quad hc_{AB} = \int_A^B \frac{g - \tilde{g}}{\bar{g}} dn \end{aligned} \quad (6)$$

Then for the three height systems we have:

- Dynamic height differences $\Delta h_{AB} = \Delta H_{AB}^d$ and height corrections $hc_{AB} = dc_{AB}$
- Orthometric height differences $\Delta h_{AB} = \Delta H_{AB}$ and height corrections $hc_{AB} = oc_{AB}$
- Normal height differences $\Delta h_{AB} = \Delta H_{AB}^*$ and height corrections $hc_{AB} = nc_{AB}$

The height differences and height corrections are given by the expressions (Hofmann-Wellenhof and Moritz 2006, Sects. 4.2–4.4)

$$\begin{aligned} \Delta h_{AB}^d &= \Delta n_{AB} + dc_{AB}, \\ dc_{AB} &= \int_A^B \frac{g - \gamma_{45}}{\gamma_{45}} dn \approx \sum_A^B \frac{g - \gamma_{45}}{\gamma_{45}} \delta n \end{aligned} \quad (7)$$

$$\begin{aligned} \Delta H_{AB} &= \Delta n_{AB} + oc_{AB}, \\ oc_{AB} &= \int_A^B \frac{g - \bar{g}}{\bar{g}} dn \approx \sum_A^B \frac{g - \bar{g}}{\bar{g}} \delta n = dc_{AB} \\ &\quad + \frac{\bar{g}_A - \gamma_{45}}{\gamma_{45}} H_A - \frac{\bar{g}_B - \gamma_{45}}{\gamma_{45}} H_B \end{aligned} \quad (8)$$

$$\begin{aligned} \Delta H_{AB}^* &= \Delta n_{AB} + nc_{AB}, \\ nc_{AB} &= \int_A^B \frac{g - \bar{\gamma}}{\bar{\gamma}} dn \approx \sum_A^B \frac{g - \bar{\gamma}}{\bar{\gamma}} \delta n = dc_{AB} \\ &\quad + \frac{\bar{\gamma}_A - \gamma_{45}}{\gamma_{45}} H_A^* - \frac{\bar{\gamma}_B - \gamma_{45}}{\gamma_{45}} H_B^* \end{aligned} \quad (9)$$

where δn are the height difference segments observed between points A and B.

For the orthometric heights, the average value of gravity along the plumb line is often approximated by use of Prey’s reduction, resulting in *Helmert orthometric heights* (or *normal orthometric heights* when the actual gravity value is unknown and is approximated by the normal gravity value):

$$\bar{g}_P = \frac{1}{H_P} \int_{P_0}^P g dH \approx g_P - \frac{1}{2} \frac{\partial g}{\partial H} H_P \approx g_P - \left(2\pi G \rho + \frac{1}{2} \frac{\partial \gamma}{\partial H} \right) H_P \quad (10)$$

For the normal heights, the average value of normal gravity along the normal plumb line can be obtained iteratively from the expression

$$\begin{aligned} \bar{\gamma}_P &= \frac{1}{H_P^*} \int_{Q_0}^Q \gamma dH^* \approx \gamma_P \left[1 - \left(1 + f + \frac{\omega^2 a}{\gamma_a} - 2f \sin^2 \phi_P \right) \frac{H_P^*}{a} \right. \\ &\quad \left. + \left(\frac{H_P^*}{a} \right)^2 \right] \end{aligned} \quad (11)$$

where ϕ_P is the geodetic latitude of point P, a, f, ω are the semimajor axis, flattening and rotational rate of the reference ellipsoid, and γ_a is the normal gravity at the equator.

Vertical Datum Definition and Realization

In the following, we will use the orthometric height system, which utilizes the geoid as its surface of zero heights, although it is also possible to work with normal heights, height anomalies, and the telluroid or the quasi-geoid. The reason for this choice is that, even in the era of GNSS positioning, most countries do not store their gravity data as gravity disturbances δg but as gravity anomalies Δg , and also because it is easier to solve the Stokes geodetic BVP rather than the Molodensy geodetic BVP; see definitions and equations in Sideris, ► “[Geoid Determination, Theory and Principles](#)”. Vertical datum unification can also be made using just geopotential numbers instead of a particular type of height system. This has the advantage that all developments can be made in terms of geopotential numbers or potential differences and then be converted into the desirable height system using the equations in the preceding section. In order to keep this entry short, however, these alternatives will not be discussed here, and the interested reader is referred to Sánchez and Sideris (2017) and Sansò et al. (2019).

Traditionally, regional and national (orthometric) vertical datums have been realized by selecting a *fundamental point* (or *origin*) $\bar{P}_0$ on the geoid surface of constant gravity potential W_0 , with $H_{\bar{P}_0} = 0, W_{\bar{P}_0} = W_0$. $\bar{P}_0$ is typically at, or connected to, a coastal tide gauge. Through levelling observations connected to $\bar{P}_0$, orthometric height differences and then orthometric heights are derived for all the points of a levelling network. This choice is due to the historical preference of measuring heights above Mean Sea Level (MSL) and the use of the geoid – the gravity field equipotential surface that best approximates the idealized MSL – as the vertical datum for orthometric heights, even though it is well known that the MSL is not an equipotential (level) surface. In order to be able to unify (connect) vertical datums referring to two different level surfaces, knowledge of their potential difference is required. Vertical datum unification by use of the MSL is in fact possible by the *ocean method* (or *ocean levelling method*), which relies on the connection of the MSL at various tide gauges by the mean dynamic topography (MDT), i.e., the height of the average sea surface above the geoid (see, e.g., Rummel and Ilk 1995; Woodworth et al. 2012). Here, we will concentrate on the *geodetic method* that uses as observables gravity measurements, orthometric heights from levelling, and ellipsoidal heights from GNSS, and determines the geoid by solving the Stokes geodetic BVP; see also Heck and Rummel (1990) and Sideris (2014).

Geodetic BVP Solutions for Single and Multiple Vertical Datums

Solution to the single (global) vertical datum geodetic BVP.

We will use here the more general version of the Stokes geodetic BVP than the one in Sideris, ► “[Geoid Determination, Theory and Principles](#)”, for an arbitrary geocentric reference ellipsoid. Namely, we assume that the normal potential of the reference ellipsoid U_0 differs from the gravity potential of the geoid W_0 , i.e.,

$$\Delta W_0 = W_0 - U_0 \quad (12)$$

and that the mass of the reference ellipsoid differs from the mass of the geoid by an amount δM . In this case, Eqs. (12) and (13) in Sideris, ► “[Geoid Determination, Theory and Principles](#)”, become (see also Hofmann-Wellenhof and Moritz 2006, Chap. 2)

$$N = \frac{k\delta M}{R\gamma} - \frac{\Delta W_0}{\gamma} + \frac{T}{\gamma} = N_0 + \frac{T}{\gamma} \quad (13)$$

$$\Delta g = -\frac{\partial T}{\partial h} + \frac{1}{\gamma} \frac{\partial \gamma}{\partial h} (T - \Delta W_0) \quad (14)$$

where k is Newton’s gravitational constant and R is the mean radius of the Earth.

The *generalized Bruns’s formula* of Eq. (13) above can be used to estimate the geoid undulation from T , and Eq. (14) is the boundary condition relating the unknown T to the data Δg on the boundary surface of the geoid Γ .

T is obtained as the solution of the Stokes geodetic BVP, which is defined by Laplace’s equation together with the boundary condition of Eq. (14) on Γ . In spherical approximation, by using a sphere with radius $r = R$, where R is the mean radius of the Earth, we obtain

$$\frac{1}{\gamma} \frac{\partial \gamma}{\partial h} \approx \frac{1}{\gamma} \frac{\partial \gamma}{\partial r} = -\frac{2}{R} \quad (15)$$

The single (global) vertical datum geodetic BVP in spherical approximation is then defined as follows:

$$\begin{aligned} \nabla^2 T &= 0, & \text{outside } \Gamma \\ -\frac{\partial T}{\partial r} - \frac{2}{R} T &= \Delta g - \frac{2}{R} \Delta W_0, & \text{on } \Gamma \\ T &= 0, & \text{at infinity} \end{aligned} \quad (16)$$

For a computational point P, the solution for T is given (spherical approximation, spherical boundary surface) by Eq. (17) in Sideris, ► “[Geoid Determination, Theory and Principles](#)”, i.e.,

$$T_P = \frac{R}{4\pi} \iint_{\sigma} \Delta g S(\psi) d\sigma = S \Delta g \quad (17)$$

Here, instead of Eq. (18) in Sideris, ► “Geoid Determination, Theory and Principles”, we will use the spherical harmonic expansion of $S(\psi)$ as it more appropriate for the developments in the section that follows:

$$S(\psi) = \sum_{n=2}^{\infty} \frac{2n+1}{n-1} P_n(\cos \psi) \quad (18)$$

where σ is the unit sphere, ψ is the spherical distance between data and computation point, P_n is the Legendre polynomial of degree n , and $S(\psi)$ is the Stokes function.

The geoid undulation at P can finally be obtained from the generalized Bruns’s Eq. (13):

$$N_P = \frac{k\delta M}{R\gamma} - \frac{\Delta W_0}{\gamma} + \frac{1}{\gamma} S \Delta g = N_0 + \frac{1}{\gamma} S \Delta g \quad (19)$$

The evaluation of the term $\gamma^{-1} S \Delta g$ in Eq. (19) is not computed by evaluating Eq. (17) directly but by the remove-compute-restore technique presented in Sideris, ► “Geoid Determination, Computational Methods” (Eq. 1). Here, for brevity, and also because we have assumed that the gravity anomalies have already been reduced onto the boundary surface, we do not provide the equations for the contribution of the topography even though they should not be omitted in areas of rough terrain. A reader interested in the detailed procedures and formulas should consult the abovementioned entries in this encyclopedia, and Sansò and Sideris (2013, Chaps. 4 and 8).

The long wavelengths of the gravity field are first removed from the data by use of geopotential model (GM), then the residual anomalies are the input to Stokes’s integral to produce residual undulations, and then the long wavelength part of the geoid is computed from the same GM and restored. The GM-contributions to Δg and N , i.e., Δg_{GM} and N_{GM_P} ,

respectively, are computed from Eqs. (2) and (3) in Sideris, ► “Geoid Determination, Computational Methods”. The residual quantities are obtained from

$$\Delta g_{res} = \Delta g - \Delta g_{GM} \quad (20)$$

$$N_{resP} = \frac{1}{\gamma} S_{res} \Delta g_{res} \quad (21)$$

where the *residual Stokes kernel*

$$S_{res}(\psi) = S(\psi) - \sum_{n=2}^{n_{max}} \frac{2n+1}{n-1} P_n(\cos \psi) \quad (22)$$

is employed in order to match the maximum degree and order n_{max} of the GM used, and the integration in Eq. (17) is carried out only to the corresponding spherical cap ψ_o around the computation point P. The N value is then obtained as

$$N_P = N_{GM_P} + N_{resP} \quad (23)$$

Solution to the multiple vertical datums geodetic BVP.

We assume that the whole sphere σ is covered by $J+1$ non-overlapping vertical datum zones $\sigma^j, j = 0, 1, 2, \dots, J$ (Rummel and Teunissen 1988). Each of these vertical datums is defined by the level surface with potential W_0^j passing through a fundamental point $\bar{P}_0^j$ (see Fig. 3). The zone σ^0 defined by $W_0^0 = W_0$ and $\bar{P}_0^0 = \bar{P}_0$ is chosen arbitrarily as the reference datum with respect to which the geopotential differences

$$\delta W_0^j = W_0 - W_0^j, \quad j = 1, 2, \dots, J \quad (24)$$

and the associated vertical datum offsets will be computed. Since we have

$$\begin{aligned} \Delta W_0^j &= W_0^j - U_0 = W_0^j - U_0 + W_0 - W_0 = \Delta W_0 - \delta W_0^j, \\ j &= 1, 2, \dots, J \end{aligned} \quad (25)$$

Height Systems, Vertical Datums and Their Unification,

Fig. 3 Geometry of multi datum geodetic BVP and datum offsets ($\bar{P}_0^j, W_0^j$ and $\delta W_0^j, \delta W_0^{j+1}$ denote datum fundamental points, datum potentials, and datum offsets, respectively)

$$\Delta g^j = \Delta g - \frac{2}{R} \delta W_0^j, \quad j = 1, 2, \dots, J \quad (26)$$

where, for simplicity, we assume the same reference ellipsoid for all datums, we see that with respect to the corresponding values for the reference datum, in datum j not only the geoid undulations N^j and the orthometric heights H^j will be biased but so will the gravity anomalies, as well (Sideris 2014). Specifically, Δg^j are biased with respect to those on the reference datum by the second term in the right hand side of Eq. (26), which can be considered as the “free-air” reduction needed to reduce Δg^j from the zero-height level W_0^j to the reference level W_0 . The more general case of different datums having different reference ellipsoids can be found, in ellipsoidal approximation, in Sansò and Usai (1995) and in Sansò and Venuti (2002).

By use of the above equations, the geodetic BVP for $J + 1$ datum zones is defined by the following equations:

$$\begin{aligned} \nabla^2 T &= 0, & \text{outside the boundary} \\ -\frac{\partial T}{\partial r} - \frac{2}{R} T &= \Delta g - \frac{2}{R} \Delta W_0 - \frac{2}{R} \sum_{j=1}^J c_p^j \delta W_0^j, & \text{on the boundary} \\ T &= 0, & \text{at infinity} \end{aligned} \quad (27)$$

where c_p^j indicates whether the computation point P belongs to zone σ^j ($c_p^j = 1$) or not ($c_p^j = 0$).

The solution of the above geodetic BVP using biased gravity anomalies is

$$\begin{aligned} T_p^j &= S \Delta g^j = S \left(\Delta g - \frac{2}{R} \sum_{j=1}^J c_p^j \delta W_0^j \right) \\ &= S \Delta g - \frac{2}{R} \sum_{j=1}^J \delta W_0^j I_p^j = T_p - \delta T_p^j \end{aligned} \quad (28)$$

from which we obtain T as

$$T_p = T_p^j + \delta T_p^j = S \Delta g^j + \frac{2}{R} \sum_{j=1}^J \delta W_0^j I_p^j \quad (29)$$

where

$$I_p^j = \frac{R}{4\pi} \iint_{\sigma^j} S(\psi) d\sigma \quad (30)$$

The geoid undulation using biased gravity anomalies referring to datum j is obtained by Bruns's equation

$$\begin{aligned} N_p &= \frac{k\delta M}{R\gamma} - \frac{\Delta W_0^j}{\gamma} + \frac{T_p}{\gamma} = \frac{k\delta M}{R\gamma} - \frac{\Delta W_0}{\gamma} + \frac{\delta W_0^j}{\gamma} + \frac{1}{\gamma} S \Delta g^j \\ &\quad + \frac{1}{\gamma} \frac{2}{R} \sum_{j=1}^J \delta W_0^j I_p^j \\ &= N_0 + \delta N^j + \frac{T_p^j}{\gamma} + \frac{\delta T_p^j}{\gamma} \end{aligned} \quad (31)$$

Hence the use of biased gravity anomalies in the solution of the geodetic BVP introduces two effects in the derived geoid: the *vertical datum offset* $\delta N^j = \delta W_0^j / \gamma$ which is a *direct bias* term on N , and $\delta T_p^j / \gamma$ which is the effect of an *indirect bias* term on N . Writing this last term explicitly as

$$\delta N_p^{j,\text{ind}} = \frac{\delta T_p^j}{\gamma} = \frac{1}{\gamma} \frac{2}{R} S \delta W_0^j = \frac{2}{R} \delta N^j I_p^j + \frac{2}{R} \sum_{i=1, i \neq j}^J \delta N^i I_p^i \quad (32)$$

we can see that the geoid height of point P in the datum zone σ^j is affected by the offsets δN^j (or δW_0^j) of all J datum zones and not only by the offset of the j^{th} one.

As in the single-datum geodetic BVP solution, the evaluation of the term $N_p^j = \gamma^{-1} T_p^j$ in Eq. (31) is not computed by Eq. (17) directly as $\gamma^{-1} S \Delta g^j$ but by the remove-compute-restore technique. The residual quantities are obtained from

$$\Delta g_{\text{res}}^j = \Delta g^j - \Delta g_{\text{GM}}^j \quad (33)$$

$$N_{\text{resp}}^j = \frac{1}{\gamma} S_{\text{res}} \Delta g_{\text{res}}^j \quad (34)$$

using the residual Stokes kernel of Eq. (22) and the N_p^j value is then obtained as

$$N_p^j = N_{\text{GMp}}^j + N_{\text{resp}}^j \quad (35)$$

It is very important to note that the residual Stokes kernel should also be used in Eqs. (30) and (32) for the computation of the indirect effect, which should be evaluated as

$$\delta N_p^{j,\text{ind}} = \frac{\delta T_p^j}{\gamma} = \frac{1}{\gamma} \frac{2}{R} S_{\text{res}} \delta W_0^j = \frac{2}{R} \delta N^j I_{\text{resp}}^j + \frac{2}{R} \sum_{i=1, i \neq j}^J \delta N^i I_{\text{resp}}^i \quad (36)$$

Finally, Eq. (31) can now be evaluated as

$$N_p = N_0 + \delta N^j + N_{\text{GMp}}^j + N_{\text{resp}}^j + \delta N_p^{j,\text{ind}} \quad (37)$$

The indirect bias term $\delta N_p^{j,\text{ind}}$ vanishes only if T is derived from unbiased gravity anomalies obtained from, e.g., a satellite-only GM. This, however, creates a non-negligible omission error in the computed value of N . Fortunately, the use of the residual Stokes kernel in Eq. (36) results in an indirect bias term that can safely be omitted as it has been shown that for any GM with $n_{\text{max}} \geq 70$, this term is below 1 cm. Numerical results for both the omission error and the indirect bias term can be found in Sideris and Fotopoulos (2012), Sideris (2014), and Sánchez and Sideris (2017).

Determination of Vertical Datum Offsets

In order to be able to determine all J unknown datum offsets, namely, δW_0^j or δN^j , $j = 1, 2, \dots, J$, together with ΔW_0 or N_0 , at least one data point P per datum zone should be given with known ellipsoidal height h_P determined from GNSS positioning and orthometric height H_P^j from levelling in the datum σ^j . This can be, for example, the fundamental point/tide gauge of each datum; see discussion in Sideris (2014). We can then form the following *observation equation* for each point P using N_P^j from Eq. (37) into Eq. (4):

$$l_P = h_P - H_P^j - N_{\text{GM}_P} - N_{\text{resp}}^j = N_0 + \left(1 + \frac{2}{R} I_{\text{resp}}^j\right) \delta N^j + \frac{2}{R} \sum_{i=1, i \neq j}^J I_{\text{resp}}^i \delta N^i + v_P \quad (38)$$

where l_P denotes the “observable” and v_P denotes the stochastic residual.

When more points than the minimum required are available, the solution is obtained by least-squares adjustment. For a set of $n \geq J + 1$ observation equations, the matrix form of the functional model of Eq. (38) is

$$l = A \delta N + v \quad (39)$$

with corresponding stochastic model

$$E\{v\} = 0, E\{vv^T\} = C_l = C_h + C_H + C_{N_{\text{GM}}} + C_{N_{\text{res}}} \quad (40)$$

where $E\{\cdot\}$ is the expectation operator, A is the design matrix, and C are variance-covariance matrices. The least-squares solution of the vector of datum offsets and their variance-covariance matrix is

$$\widehat{\delta N} = (A^T C_l^{-1} A)^{-1} A^T C_l^{-1} l, \widehat{C}_{\delta N} = (A^T C_l^{-1} A)^{-1} \quad (41)$$

The above is the general least-squares solution that can be applied to the global unification of height systems. It can also be used with, besides tide gauges, observations from GNSS/levelling benchmarks and from ocean levelling, either separately for each data group or in a combined fashion adjusting together all available data groups.

Solution simplifications and practical considerations.

Since, as already mentioned, the indirect bias term can be rendered negligible for cm-level accuracy by choosing a GM with $n_{\text{max}} \geq 70$, Eq. (37) can be simplified to

$$l_P = h_P - H_P^j - N_{\text{GM}_P} - N_{\text{resp}}^j = N_0 + \delta N^j + v_P \quad (42)$$

which makes the least-squares solution much easier to implement.

Either because of lack of information or to improve the efficiency of the computations, another simplification often applied in practice without significant loss of accuracy is the use of diagonal or block-diagonal variance-covariance matrices in Eq. (41). Examples can be found in Gerlach and Fecher (2012) and Rangelova et al. (2016).

Another often-used simplification of Eq. (38) is to set N_0 or ΔW_0 equal to zero. This is equivalent to selecting a conventional value for W_0 , either by setting W_0 equal to U_0 , or by computing W_0 with data at tide gauges or in the oceans. The approach relies on the geoid being the level surface around which the sea surface heights (SSH), H_S , are near zero when averaged globally over all oceanic regions σ_s (Gauss-Listing geoid). Mathematically, we require that

$$\frac{\partial}{\partial W_0} \iint_{\sigma_s} H_S^2 d\sigma \approx \frac{\partial}{\partial W_0} \iint_{\sigma_s} \left(\frac{W_0 - W}{\gamma} \right)^2 d\sigma = 0 \quad (43)$$

which results in the following expression for W_0 :

$$W_0 = \frac{\iint_{\sigma_s} \frac{W}{\gamma^2} d\sigma}{\iint_{\sigma_s} \frac{1}{\gamma^2} d\sigma} \quad (44)$$

The SSH is typically derived from altimetry over the oceans and W_0 can be estimated from gravity data. There are many problems to be resolved in this approach, such as the spatial coverage/integration area and choice of ocean models (typically the polar regions are left out), the choice of reference epoch and long-term variations of MSL, the choice (ideally, satellite-only) and maximum degree of a GM, plus the ones mentioned in the next paragraph (see also Heck 2005). Although this approach has its proponents (see, e.g., Burša et al. 2008; Sánchez 2008), it has not been

adopted here, on the one hand because of the inherent problems just mentioned and, on the other hand, because selecting a particular W_0 is not really necessary for global height unification, unless governments decide to reference all their data to a unified global vertical datum, which seems unlikely at this point in time.

In general, when estimating vertical datum offsets, besides knowing the error characteristics of all data sets that enter into the least-squares adjustment, care must be taken so that all data are consistent in terms of observation epoch, global terrestrial reference frame (e.g., ITRF), reference ellipsoid, height type, tide system, and crustal motion and sea-level change effects, wherever present. For example, in areas with significant crustal motion such as Canada and Fennoscandia, heights of tide gauge benchmarks should be corrected using GNSS-derived vertical crustal velocities or geophysical models of crustal motion due to glacial isostatic adjustment (Rangelova et al. 2012; Peltier et al. 2015).

Summary and Outlook

We have briefly outlined how height systems and vertical datums are defined and implemented, how they are related to the Earth's gravity field, and how they can be unified by employing the solution to the multi-datum geodetic BVP. We have shown in detail how vertical datum unification can be achieved when ellipsoidal heights from GNSS or altimetry, orthometric heights from geodetic or oceanographic levelling, and geoid heights from global geopotential models and gravity anomalies are available at each fundamental point, and/or other stations, in each of the existing national or regional vertical datums. The functional and stochastic models used for the determination of the offsets between existing vertical datums by least-squares adjustment have also been discussed, together with the theoretical and practical issues that must be considered in this estimation process. Numerical results on the unification of regional and continental vertical datums have been published in the last two decades. Such examples are the articles by Featherstone and Filmer (2012) for Australia, Amos and Feathersone (2009) and Tenzer et al. (2011) for New Zealand, Sánchez and Sideris (2017) for South America, and Sideris and Fotopoulos (2012) and Rummel et al. (2014) for Europe and North America.

Although global vertical datum unification has not been attempted systematically yet, countries in Europe, North America, and Oceania have started abandoning traditional levelling networks and adopting geoid (or quasi-geoid)-based vertical datums realizable through a geoid surface and GNSS positioning. Examples of such height modernization efforts can be found at <https://www.nrcan.gc.ca/height-reference-system-modernization/9054> for Canada, and at <https://www.ngs.noaa.gov/heightmod/> for the USA. The

effort for global unification of all of these datums is already underway, coordinated by the International Association of Geodesy (IAG) and its Global Geodetic Observing System (GGOS). A strategy for the realization of the International Height Reference System (IHRF) has already been developed (Ihde et al. 2017; Sánchez and Sideris 2017), and efforts for its implementation are currently underway by the international scientific community (IAG Joint Working Group on the Implementation of the International Height Reference Frame, IHRF) and national government agencies.

Elastic waves in heterogeneous media

Definition

By high-frequencies, we mean spatial variations in elastic properties of the medium over a distance scale much larger than the wavelength of seismic waves (i.e., heterogeneities with a scale length less than the seismic wavelength), which includes seismic wave propagation on a local to regional scale. Frequency is, therefore, an important parameter for broadly classifying seismology into three categories, each with a different scale of investigation: low-frequency (<20 mHz), high-frequency ($20\text{--}50$ mHz $< f < 1\text{--}30$ Hz), and exploration (>10 Hz) seismology. High-frequency signals are noncoherent (random), additive in terms of power/energy instead of amplitudes ignoring phase: they can be band-passed with a zero-phase filter and squared to obtain their energy content. Their waveform shapes are highly complex, where the complexity could stem from heterogeneity in source rupture process and/or complicated wave propagation effect. Source properties such as spatial variations of rupture velocity, slip velocity and stress drop, and complex wave propagation (structure) effects like reflection, refraction at interfaces separating two different media, multipath arrivals over different azimuths, focusing/defocusing of energy due to lateral changes in medium properties, attenuation (anelastic) and scattering of seismic waves could lead to the observed waveform complexity. The wave gets amplified or/and attenuated near the recording sites as they pass through unconsolidated near-surface material. Thus, accounting accurately for the improved source, wave propagation, site effects including the soil nonlinearity in ground-motion modeling offers potential benefits in more realistic region-specific seismic hazard assessment.

Introduction

The propagation of high-frequency seismic waves in a 3-D laterally heterogeneous elastic medium is a challenging problem. The complexity of resulting seismogram results from mode conversions, multipath, anisotropy, attenuation, and scattering of seismic waves and their superposition from small-scale heterogeneities encountered during wave propagation. Superposition of scattered waves results in a long-duration complex wave train following the direct wave arrival called as the coda. Given a multitude of wave propagation phenomena for their origin, a better understanding of their source of complexity is essential for detailed imaging of medium heterogeneities that requires proper identification, characterization, and origin of coda waves. The high-frequency seismic waves are very sensitive to small-scale heterogeneities in the lithosphere. These heterogeneities strongly influence seismic waves; their effects on the waveform can be studied through (1) propagation and attenuation

(decay in amplitude with distance) of direct (body and surface) and coda waves recorded at local to regional distances through the lithosphere, and (2) fluctuation in amplitude and phase of teleseismic P-wave train at ~ 1 Hz observed at a closely spaced seismic array. The teleseismic P-wave train, based on spectral analyses, is used for discriminating earthquakes from underground nuclear explosions, for early tsunami warning by fast determining magnitude, duration of events, and source rupture complexity (Wu et al. 2019).

The organization of the chapter is as follows. I present a brief introduction to the basics of seismic wave (both acoustic and elastic) propagation theory with the governing equations, standard methods of data analyses, and finally summary and outlook.

Basic Wave Propagation Principle

The fundamental theory of wave propagation primarily rests on two equations: Newton's second law (acceleration is proportional to the divergence of the stress tensor), and generalized Hooke's constitutive law stating the proportionality between stress and strain in 1-D, with an introduction of stress tensor or traction in higher dimensions (2-D and 3-D).

Acoustic Wave Propagation

For the acoustic approximation, the dominant wave type is a compressional (or longitudinal) wave with no shear contribution, governed by the following equations.

$$P = -\kappa \nabla \cdot \mathbf{u} \quad (\text{Hooke's law}), \quad (1)$$

$$\frac{\partial P}{\partial x} = -\rho(x, y, z) \frac{\partial^2 \mathbf{u}}{\partial t^2} \quad (\text{Newton's law}), \quad (2)$$

where $\mathbf{u} = (u, v, w)$ are the displacement field-components along the (x, y, z) axes, $P(x, y, z, t)$ is the spatio-temporal change in acoustic pressure wave (say, the pressure exerted by medium on face of a cube), $\kappa(x, y, z)$ is the spatially varying bulk modulus, and $\rho(x, y, z)$ is the density distribution of medium. The acoustic wave equation can be expressed as:

$$\nabla^2 P - \frac{1}{V^2} \frac{\partial^2 P}{\partial t^2} = -\frac{\rho(x, y, z)}{\kappa(x, y, z)} \ddot{f}(x, y, z, t), \quad (3)$$

$f(x, y, z, t)$ is the spatio-temporal variation of body force, double dots over it represent double time derivative, $V = \sqrt{\frac{\kappa(x, y, z)}{\rho(x, y, z)}}$ is wave speed. The solution of wave equation in 1-D is $P(x, t) = A_0 e^{i(kx - \omega t)}$, where the function $e^{i(kx - \omega t)}$ describes a right-going plane wave, k is wave number; $k^2 = (\omega/V)^2$ defines the dispersion relation linking the

temporal and spatial variables in the frequency domain. For a point source, Eq. (3) becomes:

$$\begin{aligned} \nabla^2 G(\mathbf{x}, t|\mathbf{x}', t') - \frac{1}{V^2} \frac{\partial^2 G(\mathbf{x}, t|\mathbf{x}', t')}{\partial t^2} \\ = -\delta(\mathbf{x} - \mathbf{x}') \delta(t - t'), \end{aligned} \quad (4)$$

where $\delta(\mathbf{x} - \mathbf{x}')$ is the spatially delayed Dirac delta function, with the source location at $\mathbf{x}'$, with its temporal counterpart $\delta(t - t')$ with the source excitation time t' , and t is time variable. The $G(\mathbf{x}, t|\mathbf{x}', t')$ is the response of the medium, defined between the point source $(\mathbf{x}', t')$ and the receiver $(\mathbf{x}, t)$, to the impulsive point source called as the Green's function. The solution to Eq. (4) can be expressed as:

$$G(\mathbf{x}, t|\mathbf{x}', 0) = -\frac{e^{i(k|\mathbf{x} - \mathbf{x}'| - \omega t)}}{4\pi |\mathbf{x} - \mathbf{x}'|}, \quad (5)$$

where $1/|\mathbf{x} - \mathbf{x}'| = 1/r$ is the geometrical spreading factor for body waves; the solution is similar to plane wave solution, except the wave fronts are the concentric spheres with the source at the center point $\mathbf{x}$. For a medium with intrinsic attenuation, seismic wave amplitude decays exponentially with distance, and Eq. (5) can take the form $G(\mathbf{x}, t|\mathbf{x}', 0) = \frac{e^{i(kr - \omega t)} e^{-\omega r/2VQ}}{4\pi r}$, where Q is the quality factor describing attenuation.

Elastic Wave Propagation

Wave propagation through any media having nonzero shear strength (elastic materials) more closely approximates waves propagating through the real earth, especially true while studying S- and surface waves of the full wave field. Just like for acoustic waves dealing with the compressional force and dilatational strains (i.e., volume changing), Hooke's law for the elastic medium states the proportionality between stress and strain tensors related to elastic constants.

$$\tau_{ij} = c_{ijkl} \varepsilon_{kl}, \quad (6)$$

where τ_{ij} are the components of the stress tensor (the external force applied per unit area in the i^{th} direction along the surface normal to the j^{th} direction), ε_{kl} are the components of the strain tensor, c_{ijkl} are the components of the elastic stiffness tensor of medium properties, and $i, j, k, l = 1, 2, 3$. There are 81 elastic constants corresponding to 9 different stress and 9 different strains. Symmetries in the stress (i.e., $\tau_{ij} = \tau_{ji}$) and strain tensors (i.e., $\varepsilon_{ij} = \varepsilon_{ji}$) together with conservation of energy and momentum reduce the number of independent constants from 81 to 21 (Aki and Richards 1980). For acoustic media, there is only one independent constant, that is, the bulk modulus. For elastic isotropic

media, there are only two independent constants related through (Aki and Richards 1980):

$$\tau_{ij} = \lambda \delta_{ij} \varepsilon_{kk} + 2\mu \varepsilon_{ij}, \quad (7)$$

where μ is the shear modulus, and λ is Lamé's constant.

Elastic Wave Equation

Newton's law for the elastic media can be obtained by equating the external body forces with the inertial forces as:

$$\rho \ddot{u}_i = \tau_{ij,j} + f_i, \quad (8)$$

where f_i is the i th component of the body force. After expressing stress in terms of strain tensor and other constants, the vectorial form of Eq. (8) (elastic wave equation) can be expressed as:

$$\rho \ddot{\mathbf{u}} = (\lambda + \mu) \nabla(\nabla \cdot \mathbf{u}) + \mu \nabla \cdot \nabla \mathbf{u}, \quad (9)$$

The vector wave field can be split into two potential (scalar and vector) wave fields: $\mathbf{u} = \nabla \phi + \nabla \times \psi$, where ϕ and ψ are the scalar and vector potential, respectively; this along with the constraint $\nabla \cdot \psi = 0$ can decompose Eq. (9) into two potential wave field equations mentioned below:

$$\rho \ddot{\phi} - (\lambda + 2\mu) \nabla^2 \phi = 0, \quad \text{and} \quad (10)$$

$$\rho \ddot{\psi} - \mu \nabla^2 \psi = 0, \quad (11)$$

Equations (10) and (11) above, respectively, correspond to the wave equations for scalar and vector potential wave fields, satisfied by plane P- and S-waves propagating with speeds of $V_p = \sqrt{(\lambda + 2\mu)/\rho}$, and $V_s = \sqrt{\mu/\rho}$.

Theory of Seismic Wave Attenuation and Its Effects on Seismic Waveform

Seismic attenuation is quantified by reciprocal of dimensionless quality factor Q , defined as the ratio of stored energy E to the loss of energy ΔE of a plane wave in one cycle:

$$Q = \frac{4\pi E}{\Delta E} = \frac{2\alpha V}{\omega}, \quad (12)$$

where α is attenuation coefficient, V the propagation velocity, and ω the angular frequency. Attenuation causes the wave amplitude exponentially reduced with distance, x as $e^{-\alpha x}$. The propagation of seismic waves in earth can be approximated by wave propagation in an ideal elastic solid. In reality, earth material significantly differs from elastic solid, however, because earth is absorptive, inelastic, and heterogeneous. Absorption of energy in elastic media is a linear phenomenon

(linear filter) where stress and strain are linearly related as $\sigma(\omega) = M(\omega)\varepsilon(\omega)$, where ω is angular frequency, and σ , ε , and M are stress, strain, and complex modulus, respectively. The filter, represented by M , is causal, meaning that its output σ never precedes input ε . The modulus being complex can be expressed as $M = M_1 + iM_2$ or in amplitude and phase as $M = Ae^{i\phi}$ (A is amplitude, ϕ is phase, and i is imaginary unit). Attenuation is defined as $Q^{-1} = \frac{M_2}{M_1} = \tan(\phi)$. In visco-elastic media, there is a phase shift between them; accordingly elastic modulus characterizing rock material is complex and frequency-dependent.

The velocity, density, and absorption properties of earth materials affect seismic waveforms. To accurately model the seismic wave field in real media, we need to consider seismic attenuation. Effect of attenuation can be implemented in two ways: either by using the complex velocity or by convolving dissipation operators with the synthetics computed for a purely elastic media. Several attenuation models of complex modulus or propagation velocity are available to describe wave propagation in visco-elastic media over a wide frequency range. These models describe wave propagation in terms of Q and phase velocity. Of all the models, the constant- Q , nearly constant- Q (Futterman 1962) models in seismic band are the most popular ones. The standard linear solid (SLS) is preferred in finite-difference modeling of wave propagation as stress and strain are related by differential operators, which allows computing synthetics for models with arbitrary distribution of velocity and Q values (Emmerich and Korn 1987).

In time domain, attenuation in elastic solids can empirically be defined using memory variables, where elastic moduli act as time convolution operators (Ben-Menahem and Singh 1981). The corresponding modulus in frequency domain results in complex propagation velocity giving rise to attenuation accompanied by dispersion; these phenomena are related through Hilbert transform to satisfy the causality of the propagating wavelet (Aki and Richards 1980). Depending on the complexity of the medium, several moduli can be used to model attenuation; for example, superposition of SLSs can be used to approximate constant- Q over a specified frequency range. The causal linear absorption model, where attenuation is accompanied by dispersion, can be defined in terms of frequency-dependent Q and phase velocity, V (Futterman 1962) as:

Attenuation : $Q(\omega)$

$$= Q(\omega_0) \left[1 - \frac{1}{\pi Q_0} \ln \left(\frac{\omega}{\omega_0} \right) \right], \quad \text{and} \quad (13)$$

Dispersion (frequency – dependence of phase velocity) :

$$V(\omega) = V_l \left[1 - \frac{1}{\pi Q_0} \ln \left(\frac{\omega}{\omega_0} \right) \right] - \frac{i}{2Q(\omega)}, \quad (14)$$

High-Frequency Seismology,

Fig. 1 1-D wave propagation in a layered Q structure. (a) Propagating Ricker source wavelet at different travel times in a 4-layered Q-model as an example ($Q_p = 30, 40, 50$, and 60 ; $Q_s = Q_p/2$) (b) Amplitude spectra of the source wavelet at different times, as shown in (a). Note the reduction in amplitude and loss in frequency with time because of attenuation

where ω_0 is reference frequency, $Q_0 = Q(\omega = \omega_0)$, V is complex propagation velocity, and V_l is layer velocity. This attenuation model can be incorporated into a layered earth model, for example, the plane wave reflectivity algorithm to generate seismic traces. As an example, a 4-layered attenuation structure model can generate plane waves characterized by pulses with diminution amplitude, wider spread (waveform distortion) with time (Fig. 1a); their spectra show reduced high-frequency energy of the pulse at latter time because of attenuation (Fig. 1b). Once Q of the Earth reliably estimated, deconvolution or inverse Q -filtering is performed on the seismic data to restore the high frequencies to enhance seismic resolution.

Methods of Analysis of High-frequency Seismograms

There are several techniques used for analysis of high-frequency seismograms, such as scattering and attenuation of both direct and coda waves, array or polarization analysis,

converted wave analyses, local to regional scale tomography, short-period receiver function analyses, surface wave dispersion measurements including those of ambient noise, and their combinations for imaging media with an improved resolution. Because the literature on each topic mentioned above is huge, I have limited the scope of this chapter to scattering and attenuation of seismic waves at local/regional scale.

Scattering of Seismic Waves in Heterogeneous Media

Scattering from the 3-D heterogeneities with fluctuations in velocity, density, and other elastic constants alters the amplitude and phase of seismic waves, resulting in a wave train consisting of dispersed and dissipated direct arrivals followed by scattered coda waves.

Coda Wave Analysis

Analysis of coda waves is one of the major components of high-frequency seismology for characterizing the small-scale medium heterogeneities. They are more sensitive to changes

in property of medium than the direct arrivals, sampling the medium over a larger volume. The spectral decay of coda wave exhibits similar behavior irrespective of source location, path, and distance travelled. The coda power spectrum defined as function of frequency ω and time t can be expressed as $P(\omega|t) = S(\omega)C(\omega|t)$, where $S(\omega)$ is the source spectrum, and $C(\omega|t)$ accounts for the path and site effect that is independent of distance. For longer lapse times, coda energy is uniformly distributed in a volume surrounding the source and receivers, as empirically evidenced from the common shape of band-passed coda envelopes independent of distance; the amplitude of envelope varies with source strength and site amplification. Thus, by normalizing the source spectral amplitude by coda spectra at a fixed lapse time, one can separate the effects of seismic source, propagation path, and site from the observed data (coda normalization method; Aki 1980). Using this method, the relative site and source effects (spectral differences in source radiation and site amplification, respectively) can be evaluated using observations for different sources and receivers. The coda spectral ratio of event i recorded at two nearby sites j and k (k is reference site) can represent the relative site amplification (site effect) as $\frac{A_{ij}(\omega, t)}{A_{ik}(\omega, t)} = \frac{R_j(\omega)}{R_k(\omega)}$, where coda is defined at late lapse time ($t \geq 2t_s$). Similarly, the coda spectral ratio of two events i and l of the same area recorded at site j can yield relative source radiation (source effect) as $\frac{A_{ij}(\omega, t)}{A_{lj}(\omega, t)} = \frac{S_i(\omega)}{S_l(\omega)}$. The coda amplitude is estimated from band-passed envelopes.

There are several models of coda wave generation: scattered surface waves in a 2-D unbounded, homogeneous and isotropic media (Aki 1969), singly back-scattered (SBS) waves (both surface waves in 2-D and body waves in 3-D) from heterogeneities in an unbounded, homogeneous, and isotropic media for co-located source and receiver and for lapse time more than twice the S-wave arrival time (Aki and Chouet 1975), single isotropically scattered (SIS) body waves in 3-D for a finite distance by taking geometrical spreading correction into account (Sato 1977). The above scattering models assume weak single scattering of seismic waves (Born approximation), violating conservation of energy. For explaining coda in a highly heterogeneous media, we need to invoke multiple (higher orders) scattering for energy conservation to hold well, however. Based on the analyses of S-waves of local earthquakes in >1 Hz, global observations of surface waves in <1 Hz, and S-waves from the borehole seismograms of local earthquakes in >10 Hz, Aki (1980) conjectured a broad peak in Q_s^{-1} in 0.1–10 Hz corresponding to heterogeneities of length scale ranging from a few tens of km to a few hundreds of meters for seismically active regions.

The aforementioned coda models are purely phenomenological (base on empirical observations) lacking any theoretical basis. Thus, these models cannot tell about origin of coda and also cannot interpret coda attenuation in terms of medium

properties (intrinsic absorption versus scattering). Parameter Q_c obtained is a combination of scattering and intrinsic attenuation $\frac{1}{Q_c} = \frac{1}{Q_{sc}} + \frac{1}{Q_i}$, where Q_{sc} and Q_i denote the scattering and intrinsic Q , respectively. Scattering attenuation redistributes energy to other parts of wave field within the medium, while intrinsic attenuation loses energy from wave field. One of the models accounting for both the mechanisms is the energy flux model (EFM) that assumes uniform distribution of scattered coda energy in volume behind the advancing spherical wave front (Frankel and Wennerberg 1987). The coda energy envelope based on EFM can be modeled as $E^{EFM}(r, t|f) = Bt^{-3}e^{-\frac{\omega t}{Q_i}}\left[1 - e^{-\frac{\omega t}{Q_{sc}}}\right]$, where B is a constant. For negligible scattering (large Q_{sc}), EFM approximates to the SBS model of Aki and Chouet (1975) (i.e., $Q_{i,EFM} \sim Q_{c,SBS}$). Depending on frequencies, EFM for negligible scattering does not explain the observed coda envelope well (Fig. 2). Single scattering assumptions severely overestimate the coda decay in 3-D, especially at larger distances where multiple scattering is expected (Sato et al. 2012).

Wu (1985) modeled transport of energy during multiple scattering processes of coda wave formation by applying the radiative transfer theory (RTT) in seismology. RTT describes the spatial and temporal evolution of a wavefield's energy or intensity and ignores the wave interference effect. The general form of radiative transfer equation can be expressed as (Wu 1985):

$$\begin{aligned} \frac{\partial I(\vec{r}, \Omega, t)}{\partial t} + V\hat{n}(\Omega) \cdot \nabla I(\vec{r}, \Omega, t) &= S(\vec{r}, \Omega, t) \\ - \frac{1}{\tau_s} I(\vec{r}, \Omega, t) - \frac{1}{\tau_a} I(\vec{r}, \Omega, t) &+ \frac{1}{\tau_s} \int \frac{\partial \sigma_s}{\partial \Omega'} I(\vec{r}, \Omega', t) d\Omega', \end{aligned} \quad (15)$$

where $I(\vec{r}, \Omega, t)$ is the intensity at position $\vec{r}$ propagating in direction Ω , V is the group velocity of the average (coherent) wave field, $\hat{n}$ is the unit vector in the direction of propagation, and $S(\vec{r}, \Omega, t)$ is the source function. The differential scattering cross section $\frac{\partial \sigma_s}{\partial \Omega'}$ means the energy exchanged while travelling from one direction Ω into other Ω' , τ_s is the scattering mean free time defined as the time lapse between the energy exchanges. The left-hand side of Eq. (15) represents time variation of the intensity, while right side shows the growth and decay of energy with a source term, S . At longer lapse times (several mean free times), Eq. (15), for multiple scattering, approximates to diffusion regime, where coda waves are equi-partitioned among all modes and propagation directions with a stabilized S-to-P energy ratio, while with large fluctuations in ratio at background noise level (Fig. 3a and b) (Paul et al. 2005; Margerin et al. 2009). The diffuse coda waves are characterized by a prolonged duration and a very slow coda decay (strong scattering and very low intrinsic absorption) (Sato et al. 2012).

High-Frequency Seismology,

Fig. 2 Comparison of observed coda envelope with synthetic derived from EFM at different frequencies. The EFM synthetics are shown for three different values of Q_{sc} (100: blue, 1000: green, and 10,000: red) (after Padhy and Subhadra 2010; copyright of 2020 Oxford University Press)

Since Wu's introduction of RTT in seismology, the theory has extensively been developed based on the stochastic treatment of the wave equation and numerically solved to explain propagation of both acoustic and elastic waves in random media at different scales of investigation (Padhy et al. 2007; Przybilla et al. 2006; Sato et al. 2012 and references therein). The degree of heterogeneity of lithosphere expressed in terms of isotropic scattering coefficient (1/mean free path) of S-waves varies in the range 10^{-3} to $2 \times 10^{-2} \text{ km}^{-1}$ in 1–20 Hz and is $O(10^{-4} \text{ km}^{-1})$ in sublithosphere mantle at lower frequencies (0.1–1 Hz) (Fig. 4) (Sato 2019).

A more generalized energy density of a nonabsorbing 3-D multiple scattering processes satisfies the following integral equation for energy transport (Zeng et al. 1991):

$$E(r, t|f) = \frac{W(f)\Theta(\theta, \phi)}{4\pi V r^2} H(t) \delta\left(t - \frac{|r|}{V}\right) e^{-\eta_t(f)Vt} + \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \eta_{sc}(f) E(r', t'|f) e^{-V(t-t')\eta_t(f)} \times \frac{4\pi |r - r'|^2}{4\pi |r - r'|^2} \times \delta\left(t - t' - \frac{|r - r'|}{V}\right) dt' dr', \quad (16)$$

where $W(f)$ is source energy in a given frequency band, $\eta_{sc}(f) = \frac{\omega}{Q_{sc}V}$ and $\eta_t(f) = \frac{\omega}{Q_t V}$, are scattering, and total

attenuation coefficients, respectively, $\eta_t = \eta_{sc} + \eta_i$ with $\eta_i(f) = \frac{\omega}{Q_i V}$ representing intrinsic absorption coefficient, $\Theta(\theta, \phi)$ is source radiation, and V is background velocity. The first term of Eq. (16) corresponds to direct wave propagation, while the second integral term scattered wave propagation. The second term can be approximated for the single isotropic scattering (SIS) as (Sato 1977):

$$E^{SIS}(r, t|f) \approx \frac{W(f)\eta_{sc}e^{-\eta_{sc}Vt}}{4\pi r^2} \times \frac{r}{Vt} \ln \left[\frac{r + Vt}{r - Vt} \right] H\left(t - \frac{r}{V}\right), \quad (17)$$

For $t \gg \frac{2r}{V}$, energy density decays inversely with time squared as $\frac{W(f)\eta_{sc}}{2\pi V^2 t^2}$, in agreement with the SBS model of Aki and Chouet (1975) as:

$E^{SBS}(r, t|f) \approx \frac{W(f)\eta_{sc}}{2\pi V^2 t^2} e^{-Q_c^{-1}(f)2\pi f t}$. For longer lapse times, multiple scattering in Eq. (17) approaches to diffusion as:

$$E_{dif}(r, t|f) = \frac{e^{-\frac{r^2}{4Dt}}}{(4\pi Dt)^{3/2}} H(t), \quad (18)$$

where $D = \frac{V}{3\eta_{sc}}$ defines diffusivity. An approximate solution to Eq. (16) above was proposed by Paaschens (1997) as:

High-Frequency Seismology, Fig. 3 Equipartition of energy in coda. (a) Example of a vertical component displacement seismogram of a shallow local event (M_l 2.0). (b) Variation of S-to-P energy ratio with

time. Note the stabilization of energy ratio in coda with small fluctuations (after Margerin et al. 2009; copyright of 2020 Oxford University Press)

$$\begin{aligned}
 E(r, t|f) \approx & \frac{W(f)e^{-\eta_t V t}}{4\pi V r^2} \delta\left(t - \frac{r}{V}\right) \\
 & + \frac{W(f)\left(1 - \frac{r^2}{V^2 t^2}\right)^{1/8}}{\left(\frac{4\pi V t}{3\eta_t B_0}\right)^{3/2}} G\left(\eta_t B_0 V t \left(1 - \frac{r^2}{V^2 t^2}\right)^{3/4}\right) \\
 & \times e^{-\eta_t V t} H\left(t - \frac{r}{V}\right),
 \end{aligned}
 \tag{19}$$

where $G(x) \approx e^x \sqrt{1 + \frac{2.026}{x}}$, and $B_0 = \frac{\eta_{sc}}{\eta_t}$ is the seismic albedo.

The coda wave technique, such as the Multiple Lapse Time Window Analysis (MLTWA), uses any of the aforementioned multiple scattering models for separating Q_i and Q_{sc} . In this technique, integrated energy density is analyzed over consecutive time windows from the S-wave arrival time versus source-receiver distance. The observed energy density, after correction for geometrical spreading and the effects of source and site with coda-normalization, is compared with the synthesized one obtained with a multiple scattering model by solving the equation of RTT to separate Q_i and Q_{sc} (Hoshiba et al. 2001). The MLTWA has been used with uniform and layered velocity structure (Hoshiba et al. 2001; Padhy and Subhadra 2013; Sato et al. 2012 and references therein) to

High-Frequency Seismology, Fig. 4 Frequency-dependent isotropic scattering coefficient ($1/\text{mean free path}$) of S-waves for different tectonic regimes (after Sato 2019, Fig. 1; copyright of 2020 Oxford University Press)

resolve mechanisms of attenuation; the results vary strongly with frequency depending on the model and type of data used. Because of the maximum length limitation of the chapter, I limit discussion of multiple scattering coda models here with a further reference to Sato et al. (2012) for details including more advanced realistic models of elastic waves in a layered earth structure.

Seismogram Analysis of the 1999 Chamoli Earthquake

As a case study, I analyzed few aftershocks of the 1999 Chamoli earthquake of India to examine the underlying assumptions of coda wave theory presented, and also to check the reliability of the Q_c , Q_i , and Q_{sc} factors obtained by comparing observations with synthetics for both the single and multiple scattering models of coda wave formation. Figure 5 summarizes the results. Figure 5a shows an original, vertical component of an aftershock (M_L 3.5) recorded by six stations in the source area of the 1999 Chamoli earthquake of north India. Figure 5b explains the fundamental property of coda waves: their smoothed envelope shapes are similar independent of distance, meaning that coda energy is uniformly distributed behind the

advancing wave front. The difference in envelope amplitude between different stations is related to the relative source/site effect. Figure 5c presents an example of band-passed (2–4 Hz) seismogram recorded by one of the stations RAD with different positions of coda window marked that are used by the two different single scattering models presented. Figure 5d and e presents the 3-Hz band-passed seismogram envelopes inverted for Q_c based on the SBS and SIS models, respectively, over the late (starting with twice the S-arrival time, $2t_s$) and early (starting with $1.5t_s$) coda windows marked with the best fit lines. It is worth mentioning that both the models yield almost similar Q_c values when similar coda window lengths are used. Figure 5f shows the application of the multiple scattering EFM to the 3-Hz observed envelope for resolving the intrinsic and scattering Q . The synthetic envelope (solid line), and thus, the corresponding Q_i and Q_{sc} values explain the observation reasonably good; the fit is not good near the direct S-arrival, however, which could be because of the nonisotropic source radiation that the current model does not consider. Thus, the data analyzed satisfy the assumptions of coda wave, and the Q estimates within limits can be considered reliable. We limited our application to local earthquake data, although some of the theories can be extended for analyses of regional earthquakes as well.

Methods of Coda Analysis - Aftershock records of the 1999 Chamoli earthquake

High-Frequency Seismology, Fig. 5 Methods of analysis of coda waves for estimating Q_c . Q_c and Q_{sc} based on single and multiple scattering models. (a) Raw vertical component seismograms of an aftershock record of the 1999 event recorded by six seismic stations deployed in the source area. The parameters of the event are mentioned in the title. Phases P, S, and coda are marked. (b) Distances to each station are shown against each trace. Phases P, S, and coda are marked. (c) Smoothed envelopes of the seismograms shown in (a). Note the common shape of their envelopes; their amplitudes are adjusted for inferring the shape. (d) Band-passed (2–4 Hz) seismogram recorded at station RAD is shown with the varying positions of coda window used

for estimating Q_c based on the single scattering models. (d) Q_c estimation based on the SBS model. The best fit, based on the least-squares inversion, is shown with a solid line over a late coda starting from twice the S-arrival time ($2t_s$). (e) Same as (d), but with an early coda starting at $1.5t_s$ based on the SIS model. (f) The envelope is inverted for Q_i and Q_{sc} using a multiple scattering EFM of Frankel and Wennerberg (1987). The theoretical envelope is shown with a solid line. Note that the fit between the observation and theory is good over the coda (later) portion of the envelope, but is poor near the direct S-wave arrival. The corresponding Q values are shown against each frame

Summary and Outlook

I present basic concepts of seismic wave propagation and scattering in complex heterogeneous media. High-frequency seismic waves are essential for imaging of source or internal structure of earth at a sub-wavelength scale. They are very sensitive to small-scale heterogeneities of the medium, which scatter energy and broaden the waveforms producing coda waves. Starting with observational studies, I present here commonly used modeling of coda envelope based on energy transport in multiple scattering media with random heterogeneities. Several studies on theoretical and numerical modeling of coda energy are developed for both acoustic and elastic waves in random media (Sato et al. 2012). They can be used to invert envelopes for separating scattering and intrinsic absorption and for understanding the origin of coda wave types. Most of the phenomenological coda-based methods need to be validated with studies employing physics-based high-resolution numerical approaches, although they are computationally expensive for capturing high-frequency information of the waveforms to characterize small-scale heterogeneities. The assumptions underlying the coda wave theory and thus the reliability of the Q values obtained are examined by comparing observations with synthetics for few local earthquake recordings of the 1999 Chamoli event of India, and the results are encouraging within limits.

Coda-based methods have great implications in accurate ground-motion modeling by incorporating nonlinear multiple scattering effects of the medium. In imaging with scattered wave fields, the use of 1-D velocity structure to characterize surface wave propagation at short period (~ 1 s) does not fully exploit the fine details of shallow subsurface, which needs to be revisited by considering the lateral variation in physical properties with a more appropriate 3-D structure. The source rupture complexities, as inferred from inversion of high-frequency P-wave train from a dense array of stations, can be used for tsunami warning. Overall, all high-frequency features such as the appropriate 3-D velocity structure in complex media including undulated topography, sedimentary basins, volcanoes, fault zones, etc., source rupture details considering nonspherical source radiation, and characterization of sites accounting nonlinearity of soils are essential for improved shallow subsurface imaging and accurate hazard assessment. Multiple scattering-based imaging capabilities of coda waves have also found greater success in exploration such as in migration of multiples, amplitude corrections for transmission losses, etc., by treating locally scattered wave field, overcoming the limitations of linear single-scattering imaging that conventional migrations adopt.

Impact Craters on Earth

Richard A. F. Grieve^{1,2} and Gordon R. Osinski^{1,2}

¹Department of Earth Sciences, University of Western Ontario, London, ON, Canada

²Institute for Earth and Space Exploration, University of Western Ontario, London, ON, Canada

Definition

Impact crater	An approximately circular or polygonal depression formed by the hypervelocity impact of an interplanetary body (asteroid or comet) on a planetary surface.
Shock metamorphism	Irreversible changes to rocks and minerals, resulting from the passage of a shock wave produced by a hypervelocity impact.

The Terrestrial Record

Introduction

The results of planetary exploration have demonstrated that impact cratering is a ubiquitous process that has occurred throughout solar system history. On bodies that have retained portions of their early crust, such as the Moon, older surfaces are dominated by impact craters, attesting to the importance of impact cratering in early surface and crustal evolution. The Earth is the most geologically active of the terrestrial planets and is constantly renewing its surface. As impact craters are surface features, the net result of this high level of endogenous geological activity is that most of the original population of Earth's impact craters have been destroyed. What is left is a small preservation sample. The terrestrial record, however, is invaluable in the understanding of impact processes for it is the only source of ground-truth data on the three-dimensional structural and lithological character of natural impact craters.

Most recently, for example, the results of IODP-ICDP drilling at the Chicxulub crater has contributed to the understanding of the formation of so-called peak-rings in large impact basins (Morgan et al. 2016).

Since the Apollo missions in the 1960s, the ground-truth data supplied by terrestrial impact craters has served as analogues in understanding cratering processes on the other terrestrial planets; however, at the time, impact was generally not regarded as important to Earth's evolution. This changed in 1980, with evidence for a major impact as the cause of the mass extinction event at the Cretaceous-Paleogene (K-Pg) boundary ~65.5 million years ago. The actual crater, the ~180 km diameter Chicxulub crater, was identified in 1991, underneath ~1 km of sediments in the Yucatan peninsula, Mexico. The terrestrial impact record currently stands at approximately 200 odd or crater fields, with the largest being the ~300 km diameter Vredefort structure, South Africa. Evidence of distal ejecta from over two dozen impact events, some of which can be linked to their source craters, is also recorded in the stratigraphic record. They include four strewn fields of impact glasses known as tektites, which can occur over considerable areas. For example, the Australasian strewn field, which has currently no known source crater, is in excess of $50 \times 10^6 \text{ km}^2$.

Distribution

A listing of known terrestrial impact craters, along with their properties, can be found at <http://www.impactearth.com>. The spatial distribution of known terrestrial impact structures is not random, with concentrations on the geologically stable cratons of the Australian, European, and North American continents. They are areas with relative tectonic stability and low rates of erosion. That is, they are the best available surfaces for the preservation of terrestrial impact craters. These are also regions where there have been active programs to study impact craters. Geological processes, such as differential erosion, can result in terrestrial impact craters evolving from an originally negative to a positive landform, that is, by

definition, no longer a “crater.” Thus, it is more appropriate to use the term terrestrial impact “structure,” which is not limited to a particular landform. Approximately, one-third of the known terrestrial impact structures are buried by post-impact sediments. Detected initially as geophysical anomalies, their identity was confirmed by drilling. There are a number that are now underwater and several that were formed underwater, on relatively shallow continental shelves. At present, no impact structures are known on the true ocean floors, reflecting the relatively young age and poorer geologic knowledge of this realm.

At large (>20 km) diameters, the cumulative size-frequency distribution of terrestrial impact structures is similar to that on the other terrestrial planets. This likely represents some form of steady-state condition between the formation of impact structures and their removal by terrestrial geologic processes. At smaller diameters, however, there is a deficit in the number of known terrestrial impact structures. This is due to the crushing of small impacting bodies during

atmospheric passage, the relative ease with which smaller structures can be removed by erosion or buried, and the intrinsic difficulties in recognizing smaller structures. There is also a bias in the ages of known terrestrial impact structures, with most being <200 Ma old, which also reflects the problems of preservation in the terrestrial environment.

Morphology

Unless buried almost immediately, the forms of terrestrial impact structures are generally modified from their original. There is, however, the same overall progression in form, with increasing diameter, as on the other terrestrial planets. Smaller structures have the form of a bowl-shaped depression, with an upraised rim, and a depth of $\sim 1/6$ the diameter, and are termed simple structures (Fig. 1). The exposed rim, walls, and floor define what is called the apparent crater. Beneath the apparent floor is an allochthonous breccia lens, which is roughly parabolic in cross section and floored by parautochthonous fractured target rocks. This breccia lens—

Impact Craters on Earth,

Fig. 1 Top: Oblique aerial photograph of the classic example of a terrestrial simple impact structure: The 1.2 km diameter Barringer or Meteor Crater, Arizona, USA. Bottom: Schematic cross section of a terrestrial simple impact structure, showing various lithological, structural, and morphologic attributes. Note allochthonous breccia lens, with impact-melted lithologies, partially filling the structure. D rim diameter, d_a apparent depth

parautochthonous target rock boundary defines what is called the true crater, with a depth of $\sim 1/3$ the rim diameter (Fig. 1). For simple structures, the rim diameter is ~ 10 times that of the impacting body.

As the diameter increases, there is a change in form, with increasing wall and rim collapse, as simple structures evolve into complex impact structures, with rims consisting of structurally faulted terraces (Fig. 2). Interior to the rim is a down-faulted annulus or trough, which is partly filled by allochthonous breccias and/or rocks melted by the impact. At

Impact Craters on Earth, Fig. 2 Top: RADARSAT image of the Manicouagan, Canada, complex impact structure. The annular lake is 65 km in diameter and is, in part, man-made, serving as reservoir for hydroelectric power generation. The original diameter of this partially eroded structure was ~100 km and the central peak (Mont de Babel) rises to 600 m above the level of the lake. Bottom: Schematic cross section of a terrestrial complex impact structure, indicating various lithological, structural, and lithological attributes. Example shown has a central peak and an annular ring, which may have been the original form of Manicouagan. D rim diameter, d_a apparent depth, d_t true depth, SU structural uplift, which is ~0.1 D

the center is a structurally complex central peak of parautochthonous target rocks, which is the topographic manifestation of a more extensive volume of uplifted target rocks that lie beneath the floor in the center (Fig. 2). The transition diameter from simple to complex structures is an inverse function of planetary gravity and target rock strength, with the transition occurring at a diameter of ~ 4 km in crystalline and ~ 2 km in sedimentary target rocks, in the terrestrial environment. A number of relatively young (i.e., only slightly eroded) terrestrial complex structures – Houghton, Canada; Ries, Germany; Zhamanshin, Kazakhstan – lack an emergent central peak. These structures are in mixed targets of sediments overlying crystalline basement, with the lack of a peak most likely due to target strength effects. For complex structures, the rim diameter is ~ 20 times that of the impacting body.

With still increasing diameter, a fragmentary inner ring appears, marking the transition from a central peak structure to peak-ring basin. The larger impact structures in the terrestrial environment, however, tend to be older, eroded structures that have been modified, with their current elements being structural features rather than topographic features. Chicxulub is the best-preserved large terrestrial impact structure, due to burial. As such, however, the definition of its morphological elements depends on the interpretation of geophysical data. It has an interior topographic peak-ring, a terraced rim area, and exterior ring faults and, thus, appears to correspond to the definition of a multi-ring basin, as on the Moon. Details of the physics of cratering mechanics and impact, in general, can be found in Melosh (1989) and Osinski and Pierazzo (2012).

Geology of Impact Structures

Only small, young, simple impact structures, where the atmosphere has partially slowed the impacting body, have physical evidence of the impacting body in the form of spalled fragments of iron or stony-iron meteorites, which are relatively quickly destroyed by weathering. (Equivalent-sized, weaker stony meteorites are generally crushed during atmospheric passage.) Larger impacting bodies (>100 m in diameter) impact the Earth with largely undiminished velocity. The average impact velocity of an asteroidal body is $20\text{--}25\text{ km s}^{-1}$ and cometary impacts have even higher velocities. Upon impact, most of the impacting body's considerable kinetic energy is partitioned into the target by means of a hemispherical propagating shock wave, which sets the target rocks in motion (kinetic energy) and compresses them (internal energy). A cratering flow-field is established in the target, leading to the excavation of target materials. During compression, a considerable amount of pressure-volume work is done. Not all this mechanical work is recovered on

decompression to ambient pressure and the excess is manifested as waste heat. This leads to melting and even vaporization of some of the target rocks and the destruction of the impacting body.

The transient compression, decompression, and heating of the target rocks lead to shock metamorphic effects, which record pressures, temperatures, and strain rates well beyond those produced in terrestrial regional or contact metamorphism. The exact physical conditions recorded depend of the peak pressure on impact, as determined by the impacting body's impact velocity and density, and distance from the point of impact. Given the highly transient nature of shock metamorphic processes, disequilibrium and metastable equilibrium are common. The nomenclature of shocked rocks or impactites (various melt rocks, breccias, and shocked target rocks) and the pressures required to generate particular shock metamorphic effects are summarized in Stöffler and Grieve (2007). Examples of impactites and shock metamorphic effects are well illustrated in French (1998).

The highest shock metamorphic effect preserved at impact structures is impact-melted materials (Osinski et al. 2018). They result from shock pressures >60 GPa and take the form of glass clasts in breccias, melt dikes in the floor of the structure, and lenses and coherent sheets of impact melt rock within the crater interior (Fig. 3). When crystallized, impact melt rocks have an igneous-looking matrix and are often charged with mineral and lithic debris. Compositionally, these melted lithologies can be modeled as a mixture of target lithologies, in geologically reasonable proportions. Isotopic systems, such as Sr, Nd, and Pb, mirror those of the initial ratios of the target rocks, while others (e.g., Ar) can be reset and record the time of impact. In some cases, siderophile-element enrichments above target rock levels occur, reflecting an admixture of material from the impacting body. In some cases, their relative abundances have identified the type of impacting body, for example, C-1 chondrite. In a few cases, Cr and Os isotopes have also been used to identify the impacting body. At lower shock pressures (~60–30 GPa), selective mineral melting occurs. In addition, the shock wave can destroy the internal crystallographic order of feldspars and quartz and convert them to solid-state glasses, which still have the original crystal shapes. These are “diaplectic” glasses (Fig. 3), with the required pressures being 30–45 GPa for feldspar and 35–50 GPa for quartz (diaplectic plagioclase glass is also known as maskelynite). The extremely rapid compression and then decompression also produces metastable polymorphs, for example, coesite and stishovite from quartz and diamond and lonsdaleite from graphite.

The most-documented shock metamorphic feature is the occurrence of so-called planar deformation features, particularly in quartz (Fig. 3), although they do occur in other minerals, for example, feldspar, zircon. Their utility is a function of the common occurrence and stability of quartz

in terrestrial rocks and the relative ease with which they can be observed and measured by optical microscopy. When fresh, planar deformation features are parallel planes of glass, with specific crystallographic orientations as a function of shock pressures of ~10–35 GPa. The only megascopic shock features are shatter cones, which are distinctive, striated, and horse-tailed conical fractures ranging in size from millimeters to meters (Fig. 3). They are best developed in fine-grained, structurally isotropic rocks, such as carbonates and quartzites, but more poorly developed variants can occur in coarser-grained rocks. They are most common in rocks shocked to relatively low levels, ~2–6 GPa, but can occur in rocks recording pressures as high as ~25 GPa.

Geophysics of Impact Structures

For buried impact structures, a geophysical anomaly is the first indicator of their existence, although confirmation of their genesis requires drilling and the documentation of shock metamorphic effects. The most common geophysical anomaly is a localized low in the regional gravity field (Fig. 4), due to lowering of rock density from brecciation and fracturing. In general, modeling of the gravity anomalies is consistent with the morphometric parameters of terrestrial impact structures, with the anomaly extending to the rim of the structure. The anomaly increases to a maximum of ~200–300 g.u. at rim diameters of 20–30 km (Pilkington and Grieve 1992), with the lack of further increases in magnitude at larger diameters due to lithostatic pressure closing any deep-seated impact-related fracturing. The gravity signature can be complicated by erosion and variations in target rock densities. Larger complex impact structures tend to have a central, relative gravity high, which can extend out to approximately half the diameter of the structure. This central, relative gravity high is from the uplift of originally deeper (more dense) lithologies in the structural uplift.

Magnetic anomalies are more varied. Most commonly, they are a magnetic low, with the disruption of any regional trends in the magnetic field. This is due to an overall lowering of magnetic susceptibility and the randomizing of pre-impact lithological trends in the target rocks. Larger structures commonly have high-amplitude, short wave-length anomalies in the center, due to changes to remnant magnetization in the target rocks from the effects of heat, shock, and/or post-impact hydrothermal alteration. Seismic velocities are reduced at impact structures, due to fracturing, and reflection seismic images are extremely useful in characterizing buried structures in sedimentary targets. Subsurface brecciation, fracturing, and incoherency of seismic reflectors increase toward the center of complex structures due to structural uplift, resulting in a central volume that is isotropic in terms

Impact Craters on Earth, Fig. 3 Montage of impactites. (a) The impact melt sheet of the 28-km diameter Mistastin impact structure, Canada. Note the columnar jointing in the melt sheet. (b) Impact melt-bearing breccias (glassy melt rock occurs as black clasts) at the Mistastin structure. Six-centimeter diameter camera lens for scale. (c) Shatter

cones from the Haughton impact structure, Canada. Eleven-centimeter long penknife for scale. (d) Photomicrograph (*plane light*) of Planar Deformation Features (PDFs) in quartz. Image is 0.35 mm across. (e) and (f) Photomicrograph of diaplectic quartz glass seen in plane (e) and cross-polarized light (f), respectively. Images are 5 mm across

of a reflection seismic signal. Electrical methods have been used less but, in general, there is a reduction in resistivity, which is related to fracturing. Resistivity contrasts can also

delineate lithological contacts, for example, between allochthonous breccia deposits and the fractured target rock and/or post-impact sediments.

Impact Craters on Earth, Fig. 4 Residual Bouguer gravity anomaly at the 22-km diameter Gosses Bluff impact structure, Australia, which is in the form of a symmetric gravity low, with a central, short-wave anomaly due to structural uplift. The target was a flat-lying sequence of

sedimentary rocks and the simplicity in the form of the anomaly results from the lack of major asymmetric lithological/density contrasts. Contour interval is 1 g.u.

Impacts and Earth History

The formation of the terrestrial planets by the accretion of small bodies through collisions and subsequent growth to proto-planets includes potential collisions between these proto-planets. One such collision between the proto-Earth and a Mars-sized body is currently the best working hypothesis for the origin of the Moon. Such an impact would result in an Earth-orbiting accretionary disk of material from the impacting body and proto-Earth, which was the source of volatile- and siderophile-depleted material for building the Moon. The consequences for the proto-Earth include massive remelting and the loss of any original atmosphere. Without a Moon and lunar tides, there would be little or no littoral zone, which is the most important area in the terrestrial ecosystem, to Earth's oceans. With no littoral zone, the development and

evolutionary path of Earth's biosphere would have been very different. Following planetary formation, the subsequent high rate of bombardment is attested to by the heavily cratered lunar highland crust and the formation of the very large (up to 2,500 km in diameter) multi-ring impact basins. The Earth, however, has a larger gravitational cross-section and will capture more incoming interplanetary bodies than the Moon. Thus, it has been subject to a greater number of impacts than the Moon throughout geological time, including the basin-forming impacts in the period of heavy bombardment. There have been reasoned speculation as to the potential effects of such impacts (e.g., Grieve et al. 2006), but no rocks are preserved from this period of the early Earth. Such impacts would retard any development of life on Earth but once they had subsided smaller impact events may have been beneficial for microbial life, with the generation of fertile hydrothermal

systems, impact crater lakes, and new habitats within shocked rocks and minerals (Cockell et al. 2012).

The temporal association of a large impact event (Chicxulub), world-wide ejecta, and a mass extinction at the K-Pg boundary is well established (Schulte et al. 2010). As other large impact structures have not been linked to mass extinctions in the terrestrial biosphere, it may be that there was a unique characteristic to the Chicxulub event. Sulfate-bearing rocks occur at Chicxulub, raising the possibility of massive amounts of sulfur aerosols in the atmosphere after the impact. They would reduce light levels below those required for photosynthesis for the best part of a year, with the collapse of the food chain. Chicxulub-scale impacts occur every 100 ± 50 Ma. Smaller impacts occur on shorter timescales and loading of the atmosphere with dust from craters in the 20-km size-range would be global in scale. This would not produce a mass extinction but could severely disrupt or even destroy the relatively fragile infrastructure that supports human civilization.

Past-impacts have also been beneficial for the human condition. Approximately 25% of known terrestrial impact structures have some form of natural resources, ranging from unexploited local deposits to world-class mining camps (Grieve 2012). For example, the ~ 1.5 billion tonnes of ores at the Sudbury impact structure, Canada, have so far produced over \$ 300 billion worth of metals. Approximately 50% of impact structures in hydrocarbon-bearing sedimentary basins are producers. The world-class Campeche Bank oilfield in the Gulf of Mexico produces most of its hydrocarbon products (~ 12 billion barrels of oil and > 3 trillion cubic feet of gas, since discovery) from Chicxulub-related breccias and has reserves exceeding the entire known conventional reserves of the USA.

Concluding Remarks

Although the first known recorded observations of impact craters were made by Galileo Galilei in 1609, it was not until the 1960s that the importance of impact cratering as a geological process began to be recognized. This came with the recognition of shock metamorphism and its effects on rocks and minerals and with impetus provided by the Apollo landings on the Moon. It is now widely acknowledged that impact cratering is one of the most important surface geological processes in the solar system. It has also become apparent that impact events have also played an important role throughout Earth's history, shaping the geological landscape, producing economic benefits, and affecting the evolution of life. The study of impact craters and related phenomena is relatively young when compared to other fields of scientific

study and, as such, there is still considerable potential for new and exciting discoveries.

Definition

Electrical survey	Mapping subsurface resistivity by injecting an electric current into the ground.
Resistivity meter	Instrument used to carry out resistivity surveys that usually has a current transmitter and voltage measuring circuitry.
Electrode	A conductor planted into the ground through which current is passed, or which is used to measure the voltage caused by the current.
Apparent resistivity	The apparent resistivity is the resistivity of an equivalent homogeneous earth model that will give the same potential value as the true earth model for the same current and electrodes arrangement.
Multicore cable	A cable with a number of independent wires.

Introduction

The resistivity survey method is more than 100 years old and is one of the most commonly used geophysical exploration methods. It has been used to image targets from the millimeter scale to structures with dimensions of kilometers. It is widely used in environmental, engineering, and mineral exploration surveys (Loke et al. 2013). There have been many recent advances in instrumentation and data interpretation resulting in more efficient surveys and accurate earth models. In its most basic form, the resistivity meter injects a current into the ground through two metal stakes (electrodes) and measures the resulting voltage difference on the ground surface between two other points (Fig. 1). The current (I) and voltage (V) values are normally combined into a single quantity, the apparent resistivity, which is given by the following relationship.

Instrumentation, Electrical Resistivity, Fig. 1 Basic setup for an electrical resistivity survey. The current is injected into the ground through the C1 and C2 electrodes, and the resulting voltage difference is measured by the P1 and P2 electrodes

$$\rho_a = k V/I \quad (1)$$

The apparent resistivity is the resistivity of an equivalent homogeneous earth model that will give the same potential value as the true earth model for the electrodes arrangement. The geometric factor k depends on the arrangement of the electrodes (*electrical resistivity surveys and data interpretation*). The flow of the current through the ground depends on the resistivity of the material (rocks) through which it passes and is reflected in the measured voltage values. Subsurface resistivity distribution can be mapped by making measurements with the current and voltage electrodes at different positions.

Basic Resistivity Instruments

The basic parts of a resistivity measurement system include a source of electrical current, a voltage measuring system, and the cables to connect these components to the electrodes. These components have undergone major modifications over the years to improve the efficiency of the survey procedure, the quality of the data, and to increase the depth of investigation. The power source for the current is typically a battery for shallow surveys. Some small portable resistivity meter systems (Fig. 2a) for very shallow surveys of up to a few meters depth weigh less than a kilogram (Pozdnyakov et al. 2009). A typical system (with associated cables and electrodes) for environmental and engineering surveys that uses an internal battery is shown in Fig. 2b. Such systems usually weigh between 10 and 50 kg. The current source and voltage measuring circuitry are integrated into a single unit (the resistivity meter). Such battery-based systems can provide currents of up to about 2 A and have been used for survey depths of up to about 200 m. For deeper surveys where

and engineering surveys (courtesy of Torleif Dahlin and Abem Instruments AB), (c) a schematic diagram of a system for deep surveys, and (d) schematic diagram of a vector array survey layout

Instrumentation, Electrical Resistivity, Fig. 3 Example of input current and resulting voltage signal. (Courtesy of Torleif Dahlin and Abem Instruments AB)

currents of up to 10 A are used, a petrol/diesel engine powered electric generator is usually used. Such systems can weigh several hundred kilograms and are commonly used for induced polarization (IP) surveys in mineral exploration (Truffert et al. 2019). The current transmitter is separate from the receivers that measure the potential signal (Fig. 2c).

In the interpretation of the survey data, it is assumed that a direct current (DC) is used. However, in practice, a low frequency square-wave alternating current (AC) is normally used (Fig. 3). The frequency is sufficiently low (typically less than 100 Hz) such that EM effects are negligible. Figure 3 shows an example of the shape of the input current used and the resulting voltage signal. The amplitude of the voltage signal is typically in the millivolt range, but smaller voltages can be resolved if the signal-to-noise ratio is sufficiently high or signal stacking techniques are employed. A 24-bit ADC (Analog-to-digital converter) is widely used in modern systems to digitize the voltage signal. In the absence of an input current, the ground has a natural self-potential (SP) voltage between different points on the surface (*Geoelectricity*). This can be caused by variations in the chemical properties of the soil or currents induced by changes of the geomagnetic field with time. The SP voltage can vary significantly with time. The voltage measuring system in the resistivity meter has a SP buck-out mechanism to remove the SP voltage signal. It usually also has notch filters (e.g., 50, 60, 16.7 Hz) to remove noise due to electric power lines and other technical infrastructure such as electrified railway systems.

IP surveys are widely used in mineral exploration, and recently there has been increasing interest in the environmental and engineering sector (Dahlin and Leroux 2012). While both time and frequency domain (Telford et al. 1990) measurement techniques have been used in mineral exploration, the time domain method appears to be the norm for

the less powerful equipment used in environmental and engineering surveys.

Electrode Types

Metal stakes (Lu and Macnae 1998) are commonly used for the current electrodes as well as the potential electrodes in resistivity surveys. For some ground conditions where it is difficult to insert a stake electrode, flat-base (or plate) electrodes have been used (Athanasios et al. 2007); galvanic contact with the ground is achieved using an electrically conductive gel or mud at the base of the electrode. In IP surveys, nonpolarizable electrodes (Telford et al. 1990) are widely used as the potential electrodes to reduce SP noise. There has, however, been significant progress in using normal steel stakes as the potential electrodes (Dahlin and Leroux 2012) with multielectrode systems for IP surveys.

Multielectrode and Multichannel Systems

The development of multielectrode systems over the past 25 years has sparked a revolution in resistivity surveying. The advent of 2-D and 3-D (three-dimensional) resistivity tomography has opened up whole new application areas to electrical methods. Before the early 1990s, the electrical resistivity method was mainly used in resistivity sounding, profiling, and mapping surveys (Telford et al. 1990). Quantitative interpretation was mainly confined to 1-D (one-dimensional) structure of the subsurface consisting of horizontal layers (Keofoed 1979). The multielectrode systems made it practical to carry out two-dimensional imaging surveys that give a more accurate picture of the subsurface (Loke et al. 2013). A multielectrode system has about 25 or more electrodes connected to the resistivity meter via a multicore cable (Fig. 4). A switching circuitry controlled by an internal microcomputer within the resistivity-meter automatically selects the appropriate four electrodes for each measurement using a software program. Several variants of the multielectrode cable system exist, where the distinguishing factor tends to be the physical location of the switching circuitry. Some resistivity meters contain all the switching capability within the main unit, so that two or more long multicore cables are attached directly to the meter. The cables merely provide a galvanic contact between the meter and the ground. These systems have a practical limit on the number of electrode takeouts (commonly 32) in each cable. In second type of system, an external switch box is connected to the main meter via a

Instrumentation, Electrical

Resistivity, Fig. 4 Schematic diagram of a multielectrode system used for a two-dimensional electrical survey and an example sequence of measurements used to build up a pseudosection using the Wenner array

system bus. The switching capacity can then be extended by daisy-chaining switch boxes, each connecting to cable segments with multiple “dumb” electrodes. This design can vastly increase the possible number of electrodes available for simultaneous measurements, but it can also be less portable than the first arrangement, particularly in forested and rugged terrain. The third type of system uses “intelligent” electrodes, where the switching circuitry is de-centralized and placed at individual electrodes. Even the actual voltage measurement and analog-to-digital conversion may be carried out locally in such systems, potentially reducing interference problems (Stummer and Maurer 2001). Parsekian et al. (2017) have conducted experiments comparing many common multielectrode systems.

A recent development is multichannel capability for multielectrode systems that can greatly reduce the survey time. Only two electrodes can be used as the current electrodes at a single time, but the voltage can be measured between different pairs of potential electrodes. Commercial systems with four to ten channels are available and some research systems have more than 100 channels (Zhe et al. 2007; Rucker et al. 2014). New systems have been developed which transmit multiple current signals and can make several hundred measurements at a single time (Inazaki et al. 2015).

The multichannel multielectrode systems have been adapted for continuous profiling in water-covered areas

using electrodes attached to a cable pulled by a boat (Rucker and Noonan 2013; Simyrdanis et al. 2018). A PC coordinates the resistivity meter system data acquisition together with a GPS and water depth sounder. Continuous measuring systems for land surveys using cylindrical electrodes or spiked wheels to achieve continuous galvanic contact with the soil have also been developed (Loke et al. 2013).

Full-Waveform Systems

There has been considerable research on systems that record the full-waveform of the potential signal in an effort to extract more information from the data and to improve the signal-to-noise ratio using signal processing techniques (Zhe et al. 2007; Truffert et al. 2019). This is often the only practical approach for resistivity surveys in which large depths of investigation are required or where the nature of the target requires large dipole offsets. Efforts have been made to extract additional information about the subsurface IP characteristics from the full decay curve (Fiandaca et al. 2013). There have been renewed interest in vector array IP surveys (Truffert et al. 2019) using a distributed layout where each potential station has three electrodes that measure two components of electric field at right angles (Fig. 2d).

Instrumentation, Electrical Resistivity, Fig. 5 Types of capacitively coupled systems. (a) Line antenna (courtesy of Geometrics Inc.) and (b) plate-wire capacitive sensors (electrostatic quadrupole) arranged in a towed array. (Courtesy of British Geological Survey, NERC)

Capacitively Coupled Systems

Capacitively coupled systems use an oscillating, non-grounded electric dipole to generate current flow in the ground and a second similar dipole to measure the resulting potential distribution at the ground surface (Kuras et al. 2006) in areas where it is not possible to inject a galvanic current. Capacitively coupled sensor arrays allow the imaging of highly resistive targets in hardrock environments (Kuras et al. 2019; Murton et al. 2016). Mudler et al. (2019) describes making broadband spectral measurements with a new generation of capacitively coupled instrumentation, which can deliver complementary information for the characterization of the cryosphere compared to conventional low-frequency techniques.

Two major configurations have been used in mobile instruments with capacitively coupled sensors. The first configuration (line antenna type) uses cylindrical transmitters and receivers which are towed behind an operator (Fig. 5a). It gives measurements that are comparable to the galvanically coupled in-line dipole-dipole array (Kuras et al. 2006) and have maximum depths of investigation of 1–20 m. However, specially designed systems have been

used for surveys for depths of up to about 100 m in mineral exploration (Hildes et al. 2005). The second type (electrostatic quadrupole) uses flat metallic conductors (Fig. 5b) in an equatorial dipole-dipole configuration (Kuras et al. 2007) which has been used for survey depths of up to a few meters. Both configurations are dynamic measuring systems where the array configuration is fixed but the entire setup is moved during the survey for lateral coverage. Two-dimensional and three-dimensional surveys with dense lateral coverage can be rapidly conducted with these systems (Kuras et al. 2007).

Automated Resistivity Monitoring Systems

Automatic PC-controlled monitoring systems have been developed for detecting transient phenomena such as water seepage from dams, landslides, and solute transport (Uhlemann et al. 2017; Poje et al. 2018). These dedicated monitoring systems are becoming increasingly sophisticated and are now being deployed remotely with permanently installed electrode arrays, telemetric control, and data transfer, supported by automated data management systems to handle the large data

volumes generated through time-lapse data acquisition (Uhlemann et al. 2017). Other key developments include the production of low-power (e.g., 10 W) systems that are able to operate for long periods of time in the absence of mains electrical power and reactive monitoring capabilities where intensive resistivity measurements can be triggered by other environmental sensors such as rain gauges (Chambers et al. 2016).

Summary

There have been major advancements over the past few decades in the instrumentation for the electrical resistivity method. In addition to traditional one-dimensional surveys, the new multielectrode and multichannel systems have made it possible to efficiently carry out two-dimensional and three-dimensional imaging surveys that provide more accurate models of the subsurface geology. Computerized dynamic towed systems can map large areas on land and water rapidly. Capacitively coupled systems make it possible to survey areas with resistive surfaces where conventional galvanic systems cannot be used. Sophisticated PC-controlled monitoring systems are now available to automatically detect and record transient phenomena.

EM	Electromagnetic
CSEM	Controlled source EM
GDS	Geomagnetic depth sounding
MT	Magnetotelluric
SNR	Signal to noise ratio
ADC	Analog to digital conversion

Introduction

Here we look at instrumentation used for land and marine electromagnetic (EM) induction studies of Earth, which seek to characterize the electrical conductivity of the subsurface. Conductivity is driven by porosity and fluid content in the crust, temperature and mineralogy in the mantle, and minor proportions of highly conductive graphite, oxides, or sulfides in both. The principal tool for deep Earth conductivity sounding is the *magnetotelluric* (MT) method, in which time series measurements of the surface horizontal magnetic and electric fields are recorded and converted into a frequency-dependent transfer function. Loosely speaking, variations in the external magnetic field act as the input and induced electric fields in the earth act as the output. The frequency dependence of the amplitude and phase of the transfer function may be interpreted to recover electrical conductivity as a function of depth; longer periods propagate into deep structure while higher frequencies are absorbed in shallow structure. Station location constrains lateral variations in conductivity.

A related method is called *geomagnetic depth sounding* (GDS), in which a transfer function between the vertical and horizontal magnetic fields is used in a similar manner. In the past, arrays of portable GDS magnetometers were deployed to image lateral conductivity structure. Today, the main use of GDS is from data collected by magnetometers at

observatories and on magnetic satellites and used to image Earth structure at depths beyond the reach of the MT method. If assumptions are made about the morphology of the external magnetic source field, or estimates of the external field are made from the data themselves, then long period transfer functions can be interpreted to recover conductivity as a function of depth in a similar manner to MT data.

When near-surface crustal geology is of interest, man-made sources of EM energy (transmitters) can be used to probe conductivity, using either current passed through a grounded wire (an electric field source) or current passed through a loop (or loops) of wire (a magnetic field source). Electric or magnetic fields are measured as a function of transmitter frequency (frequency domain sounding) or, alternatively, transmitter turn-off time (time domain, or transient, sounding). Transmitter-receiver position, separation, and geometry (orientation, etc.) are also survey parameters. Measurements of this type fall into the category of controlled-source EM (CSEM) methods, although particular configurations often have distinct names or even trade names (e.g., Turam, LoTEM, SkyTEM).

Electric Field Measurement

Electrodes are used to make contact with the ground (or, in the marine case, seawater) for the purpose of making a measurement of potential difference, which is usually then divided by the electrode separation to form an estimate of electric field. Even with high input impedance amplifiers, some small current must be drawn to make the measurement. The simplest electrode is a metal rod in contact with damp earth or water, which will act as a source or sink of electrons e^- through the reaction.

where M is the metal and M^+ is the metal cation. This is called an electrode of the first kind, and unless the metal cation is highly concentrated in the vicinity of the electrode, this reaction will not be reversible and the electrode will polarize, creating unwanted galvanic potentials and contributing to noise. This may be tolerable for high frequency measurements, and simple metal rods are used for high frequency MT measurements using man-made radio transmitters as the source field.

If the metal rod is immersed in a concentrated aqueous solution of a compatible salt, then the reaction is reversible and the electrode is non-polarizing. The most commonly used electrode of this type is the copper-copper sulfate “porous pot.” The “pot” containing the copper sulfate solution has a semipermeable barrier as its base, usually unglazed ceramic, which makes electrolytic contact with any moisture in the

soil. Such electrodes are commonly used for broadband MT measurements in the frequency range of 1 mHz to 100 Hz.

Non-polarizing electrodes of the second kind are made by coating a metal with a sparingly soluble salt and immersing in an aqueous electrolyte containing a compatible anion. The reaction here is

where A^- is the anion. On land the most commonly used electrode of this type is lead-lead chloride immersed in solution of potassium or sodium chloride (e.g., Petiau 2000). For marine work silver-silver chloride immersed in seawater, which contains about 30 g/l sodium chloride, is commonly used (e.g., Constable 2013), and recently silver chloride electrodes have been manufactured for use on land. Silver chloride electrodes have lower temperature coefficients and higher stability than those of the first kind, and are preferred for long-period MT work on land and almost all MT studies in the marine environment. Silver-silver chloride electrodes are also favored for marine CSEM soundings, although polarizing, capacitively coupled, electrodes such as the carbon fiber sensors of Crona et al. (2001) have been used.

Electrodes are separated by cables of order 100 m long on land to integrate the electric fields and provide a measurable potential difference. Contact impedance for electrodes can be as large as several kilohms, and so the input impedance of amplifiers should be large, but gain need not be very high since signals will be up to several millivolts across a 100-m antenna, and a reasonably well-designed amplifier will not contribute significantly to noise.

For marine measurements the situation is very different. The electrode contact impedance is much lower (around 10 Ω), the signal levels are much smaller (a few $\mu\text{V/m}$), and the antenna lengths are usually shorter as well (around 10 m). For long period MT simple amplifiers with gains of about 100 are adequate, but for broadband MT and CSEM measurements at frequencies of 0.1 Hz and above, capacitively coupled chopper amplifiers with very low noise and gains of 10,000 and higher are used (Constable 2013).

Magnetic Field Measurement

Magnetic field sensors fall into two broad categories: total field magnetometers and vector magnetometers. Total field proton and nuclear precession devices are used for magnetic mapping, but for EM induction vector measurements are needed, using either induction coils or fluxgate sensors. Superconducting (SQUID) magnetometers have been used for induction studies, but so rarely that they will not be discussed here.

A simple loop of wire can be used as a magnetic sensor based on Faraday's Law, in which a time-varying magnetic field B creating a magnetic flux through area A will induce a voltage V in a loop of wire with N turns:

$$V = -NA \frac{dB}{dt} = -NA\mu \frac{dH}{dt}$$

where H is the magnetizing field and μ is permeability, which for an air-cored loop is the free-space value of $47\pi \times 10^{-7}$ H/m.

For CSEM operations at high frequencies (kilohertz range) the derivative term is large enough that an adequate signal may be measured in this way, particularly for single frequency CSEM in which lock-in amplifiers can be used. Alternatively, for time domain studies in which a large loop of wire is used as the transmitter, the area may be as much as 10^4 m^2 and it is possible to make measurements using the transmitter loop after switch-off. Normally however, induction coils (also called search coils, Fig. 1a) are used, in which thousands of turns of wire are wound around a magnetically permeable core of soft ferrite or iron-nickel alloy (permalloy or mu-metal). The core captures the magnetic field and multiplies the flux by an effective permeability μ_e , determined by a combination of geometry and relative permeability, producing a voltage

$$V = -NA\mu\mu_e \frac{dH}{dt}.$$

For long, cylindrical, highly permeable cores of length L and diameter d the effective permeability depends only on geometry and is given approximately by (Tumanski 2007):

$$\mu_e = \frac{(L/d)^2}{(\ln(2L/d) - 1)}.$$

We see that increasing length improves sensitivity, and typical broadband MT coils are of order 1 m long. The main source of noise for induction coils is the thermal (or Johnson) noise of the resistance in the wire windings, and so increasing N does not necessarily increase the signal to noise ratio (SNR) because it also increases resistance. Indeed, to a first approximation the SNR is proportional to the mass of copper used in the windings. However, if weight is an issue, as it may be for marine instruments, aluminum windings can be used for a significant improvement in weight at a modest cost in resistance noise. The noise of a good-quality induction coil used for EM induction studies is around $10^{-9} \text{ nT}^2/\text{Hz}$ at 1 Hz with a red $1/f$ type spectrum. Since motion in Earth's magnetic field can also produce a time-varying signal, on land induction coils are usually buried during operation to prevent

Instrumentation, EM,

Fig. 1 (a) Schematic depicting the operation of an induction coil magnetometer. A coil of wire is wound around a permeable core. (b) The ring-core fluxgate magnetometer. An excitation coil drives the core into saturation in two different directions. The direction aligned with the external magnetic field will saturate sooner than the direction apposed to the field, creating a pulse of unbalanced flux twice per excitation cycle, which is detected by a synchronous amplifier tuned to twice the excitation frequency. In practice, fluxgates are often used as null sensors with the output of the pickup coil used to null the field using a feedback coil; the current in the feedback coil becomes the measurement

movement. For marine MT and CSEM studies, the magnetometers must be stabilized by heavy anchors, usually made from concrete to avoid magnetic contamination.

Although integrating amplifiers or feedback can be used to flatten the frequency response of induction coils, the one-pole low-cut response of the dH/dt term is a fairly good match to the red spectrum of natural magnetic field variations. However, reasonable signal to noise performance for induction coils is still limited to periods shorter than several thousand seconds. For longer period MT and GDS studies, fluxgate magnetometers are preferred. Fluxgates use the principle that variations in magnetic flux may be generated for a fixed magnetic field by varying the effective permeability of the core material:

$$V = -NA \frac{dB}{dt} = -NA\mu \frac{d\mu_e}{dt} H.$$

This is achieved by winding the permeable core with an excitation coil which saturates the core in alternate directions using a sinusoidal or square wave current of around 1 kHz. A saturated core has an effective permeability of zero, since it is no longer influenced by the external field H , and so the excitation current generates the time-varying permeability required to get an inductive response.

Various core geometries can be used for fluxgates, but the most common type of geophysical sensor uses a ring-core geometry (Fig. 1b). The excitation coil saturates the two sides of the core symmetrically in opposite directions; the side of the coil excited in the same direction as the external magnetic

field saturates sooner, while the opposite side saturates later. This asymmetry produces a time varying net flux at twice the excitation frequency, which is detected by a pickup coil wound around the core; the orientation of the detection coil determines the direction of sensitivity. A lock-in amplifier tuned to twice the excitation frequency will thus have an output proportional to the external field. However, this output is only linear over a range of several hundred nanotesla, and also will be sensitive to variations in μ and μ_e caused by temperature, so most observatory quality instruments are operated as null sensors. The total magnetic field (usually the component of Earth's field aligned with the sensor) is cancelled by a solenoid or Helmholtz coils. The output of the fluxgate is fed back to control the current in the nulling coils, and this current then becomes the measurement of low frequency changes in the magnetic field.

The effective permeability of a ring-core of diameter L and thickness d is approximately

$$\mu_e = \frac{L}{d}$$

for large L/d ; ring-core sensors are usually about 2 cm in diameter and a millimeter or so thick, with quoted noise levels of order 10^{-4} nT²/Hz at 0.1 Hz (Primdahl 1979). By design, fluxgates sense the static magnetic field component in a given direction, which is typically 40 μ T on Earth (possibly as large as 60 μ T), and so the low-frequency response of fluxgates extends to DC. Excitation frequencies are high enough that variations up to a few tens of hertz can be recorded, but long

period MT instruments typically sample only at about 1 Hz, since the noise in fluxgates becomes higher than induction coils at a frequency of about 0.01 Hz. Also, making measurements of field variations in the presence of Earth's total field requires a large dynamic range, and with 24-bit analog to digital conversion (ADC), the least count will be of order 0.01 nT, and resolutions of 0.1 nT are more typical. Least count for an induction coil sensors are of order 0.01 pT.

EM Transmitters

Either a magnetic or electric field transmitter can be used for CSEM soundings. Electric transmitters consist of a long (hundreds of meters) wire grounded at both ends, through which a modulated current is driven. For large currents it is easier to switch square waves than generate sinusoidal waveforms, and if the switching is controlled rapidly then time domain measurements may be made. Alternatively, a swept or random sequence of binary pulses can be used and the receiver data deconvolved to generate a broadband response. For marine CSEM surveys, the high conductivity of seawater allows transmitter currents of up to a thousand amps to be used (Constable 2013). Magnetic transmitters consist of large loops of wire through which a current is passed, and are mainly used for time domain studies in land and airborne systems.

Data Acquisition Systems

The science and technology behind EM sensors have not changed significantly for many decades, but development of modern electronics has revolutionized the way MT and CSEM data are collected. The advent of microprocessors; 24 and 32 bit ADC modules; low power, high capacity, static digital memory; and the global positioning system (GPS), which allows time to be measured with microsecond accuracy anywhere on the surface of Earth, together allow continuous, time-synchronized, measurements to be made using small, portable, low power logging systems.

Time synchronization is important in MT data acquisition, since noise reduction in processing raw time series to frequency domain response functions depends on cross-spectra being estimated between two or more remotely separated sites. For CSEM soundings, synchronous stacking and estimation of phase lag between source and receiver both demand good timing for the transmitter and receiver. In the past this was done with wired or wireless links between sites for both CSEM and MT. Now, all sites can be individually clocked with GPS timing for later synchronous processing, at least on land. Marine MT and CSEM receivers must have installed clocks that are reset using GPS time before deployment, and

whose drift can be determined using GPS on recovery. In this way time accurate to better than a millisecond per day can be achieved. Since marine EM transmitters are attached to, and powered by, ships, GPS time can be used to control the output waveforms.

Similarly, in the past wired or wireless connections between the measurement equipment and bulky data acquisition and storage systems were needed, but now data can be stored site by site or even channel by channel, using integrated microprocessor controlled acquisition and solid state memory. Clearly, this has been of huge benefit to the collection of marine data, but land acquisition now also routinely uses this approach.

Navigation

The GPS system, as its name suggests, provides highly accurate locations and makes surveying land MT and CSEM stations straightforward. For marine MT and CSEM, the positioning of seafloor receivers is more difficult, since during deployment they will drift 50–100 m from the release point as they sink down through currents in the water column. For MT surveys the release point may provide sufficient accuracy, but this is not the case for CSEM surveys. In this case accurate positions need to be derived from acoustic ranging from the survey ship, whose position is known from GPS. Short (1–10 ms) and high frequency (10–100 kHz) pulses of sound are emitted from the ship and transponders on the receiver instruments reply to these with similar “pings.” The two-way travel time, along with estimates of sound speed in water derived from oceanographic tables or direct measurement, is used to calculate range. Two approaches are possible; long baseline surveys involve triangulation using ranges from three or more ship positions, and short baseline surveys use equipment which can estimate direction as well as range using multiple units or elements for the ship's transponders. For marine CSEM transmitter navigation, short baseline measurements are supplemented by depth, height, and possibly inertial sensors on the transmitter.

On land the orientation of sensors is measured or set using levels and magnetic compasses during installation (fluxgate sensors can act as their own compasses). For seafloor measurements, orientation needs to be estimated using recording tiltmeters and compasses.

Summary

Recordings of natural or man-made variations in the magnetic field may be made with fluxgate sensors or induction coils, depending on the frequency of interest. In terms of signal to noise, the crossover between the two sensors is about 0.01 Hz,

with induction coils used for measurements higher than 1 mHz and fluxgates for measurements lower than 1 Hz. Exact frequencies depend on the particular equipment and application. Electric field sensors are typically made using pairs of non-polarizing electrodes to make contact with ground or water, separated and connected to amplifiers by 10–100 m of wire. At high frequencies simple metal rods may suffice as electrodes. Modern electronics and timing derived from the global positioning system have made data collection using autonomous loggers standard for both land and marine MT and CSEM data acquisition.

International Geophysical Year

Ralph W. Baird
Baird Petrophysical International, Houston, TX, USA

Definition

The International Geophysical Year (IGY 1957–1958) was the most successful global effort to coordinate the measurement and collection of geophysical data from around the world during a period of anticipated maximum solar activity. It was also timed as a continuation of a series of international efforts to collect data at the poles, called the International

Polar Years I and II (IPY 1882–1883 and IPY 1932–1933). The IGY was planned for 18 months, July 1, 1957, through December 31, 1958, and then a follow-on organization, the International Geophysical Cooperation (IGC 1959) was necessary to complete the work and assemble the results, from January 1, 1959, through December 31, 1959.

During 2007–2009, there was a fourth international effort referred to as IGY-2 or IGY + 50. But instead of a coordinated singular management initiative, it was organized as separate initiatives; the Electronic Geophysical Year (eGY 2007–2008), the International Polar Year (IPY 2007–2008), the International Heliophysical Year (IHY 2007–2009), and the International Year of Planet Earth (IYPE 2007–2009). To capture the work and materials from the IGY 1957–1958, organizers of the IHY created a legacy archive and recognition program entitled IGY Gold. During and after the IGY 1957–1958, the non-science public joined the scientists with pamphlets, magazine articles, films, children's toys, games, and books, all aimed at encouraging exploration and discovery.

Introduction and Concept

A lack of knowledge of natural Earth processes and the interest by thousands of Earth scientists to explore and discover relationships of the processes, combined with modern communications and global transportation improvements, inspired and motivated the organizers and participants of IGY in a postwar world (the early 1950s). The more measurements were studied, the more questions evolved. To get the answers, the world Earth science community needed to cooperate and collect data together and facilitate a means to share this new data to enable new Earth science discoveries.

The concept seems simple today in the twenty-first century: propose global efforts to collect physical and chemical measurements of the Earth on a semicontinuous basis over a specified period of time. In the early 1950s, this task was burdened with a lack of infrastructure and a lack of resources in all parts of the Earth, governed by separate regimes speaking hundreds of different languages and recovering from wartime conflicts. Just getting from point A to point B was a time-consuming task. All this was about to change.

History

While in Maryland, James Van Allen (1914–2006) and his wife Abigail hosted a dinner on April 5, 1950, for British geophysicist Sidney Chapman (1888–1970), a theoretical physicist interested in the Earth's magnetic phenomena and a participant in IPY II 1932–1933. Also present at dinner was Lloyd Berkner (1905–1967), a former radio engineer who had

been on Admiral Byrd's 1928–1930 Antarctic expedition. According to Van Allen, the dinner conversation ranged widely over geophysics and especially geomagnetism and ionospheric physics. Following dinner, as they were all sipping brandy in the living room, Berkner turned to Chapman and said, "Sydney, don't you think it is about time for another international polar year?" Chapman immediately embraced the suggestion, remarking that he had been thinking along the same lines himself (Van Allen 1998).

The time was ripe. Technological improvements in instrumentation and rocketry had enabled scientists to probe much farther into the atmosphere and deep into the Earth. In the process of enlisting support among the international scientific societies, Chapman and Berkner found a strong preference for a global program encompassing additional geographical regions and additional physical science disciplines.

Chapman first presented the idea for a third IPY to the member scientific unions of the International Council of Scientific Unions (ICSU). The unions, in turn, presented the proposal to the ICSU General Assembly, and ICSU, in turn, invited the World Meteorological Organization (WMO) to participate as well as the national organizations adhering to ICSU. By 1953, there were 26 countries signed up in what came to be known at the International Geophysical Year 1957–1958. The disciplines included most of the Earth, atmospheric, and oceanic sciences, covering many parts of the globe beyond the polar regions.

Scope

By 1954, the IGY organizing committee (set up by ICSU in 1952) was known as CSAGI after its French name, Comité Spécial de l'Année Géophysique Internationale. The CSAGI established goals for IGY projects to address several areas of specific interest:

- Problems requiring concurrent synoptic observations at many points involving cooperative observations by many nations.
- Problems in the geophysical sciences whose solutions would be aided by the availability of synoptic or other concentrated work during the IGY.
- Observations of all major geophysical phenomena in relatively inaccessible regions of the Earth that can be occupied during the IGY because of extraordinary effort during that interval (the Arctic and Antarctic).
- Epochal observations of slowly varying terrestrial phenomena.

These were not arbitrary or unreasonable criteria. Based on this defined planning and framework, the scope of the IGY program materialized, and the process to organize field

operations, data collection synchronization, data reporting, and assembly and archiving began.

Operations

When comparing the organization of IGY to today's professional and scientific working groups, the IGY was controlled by two separate bodies, the CSAGI and the ICSU. Areas of science emphasis covered:

Meteorology	Cosmic Rays	Gravity
Geomagnetism	Glaciology	Nuclear Radiation
Aurora and Air Glow	Oceanography	Latitude and Longitude
Ionosphere	Rockets and Satellites	World Days and Communication
Solar Activity	Seismology	

Participating countries represented in expeditions or contributing and sponsoring in-country data collection included:

Afghanistan	German Democratic Republic	Norway
Argentina	German Federal Republic	Pakistan
Australia	Ghana	Panama
Austria	Greece	Peru
Belgium	Guatemala	Philippines
Bolivia	Haiti	Poland
Brazil	Hawaii	Portugal
Bulgaria	Honduras	Rhodesia and Nyasaland
Burma	Hungary	Romania
Canada	Iceland	San Salvador
Ceylon	India	Saudi Arabia
Chile	Indonesia	Spain
China (Nationalist)	Iran	Sudan
China (People's Republic)	Ireland	Sweden
Colombia	Israel	Switzerland
Costa Rica	Italy	Thailand
Cuba	Japan	Tunisia
Czechoslovakia	Korea, Democratic Republic of	Turkey
Denmark	Libya	Union of South Africa
Dominican Republic	Malaya	Union of Soviet Socialist Republics
East Africa	Mexico	United Kingdom
Ecuador	Mongolia, People's Republic of	United States of America
Egypt	Morocco	Uruguay
Ethiopia	Netherlands	Venezuela
Finland	New Zealand	Vietnam, Democratic Republic of
France	Nicaragua	Vietnam, Republic of
		Yugoslavia

Achievements

General achievements of IGY were:

- Global cooperation for improved Earth physical and chemical measurements.
- Improved awareness and understanding of Earth processes.
- Coordinated collection and assembly of multidisciplinary data.
- Archive and sustainable safekeeping of collected and shared data.
- Inspiration and hope for future similar programs and initiatives.

Some of the most significant IGY achievements were:

- Defining the system of mid-ocean ridges that encircle the globe, furthering our understanding of the Earth's crust and the theory of plate tectonics.
- Discovery of the Van Allen radiation belts. These belts surround the Earth at altitudes of hundreds and at thousands of kilometers above the surface and are significant to present-day electronic communications.
- Collection of synoptic data, a comprehensive overview of global physical phenomena. These achievements were accomplished through organization of various scientific fields under the International Council of Scientific Unions (ICSU). This union created a series of technical panels with scientific goals and facilitated international cooperation.
- Under the collection of synoptic data, special attention was given to the Antarctic continent. Neither the race for the South Pole in the early 1900s nor the age of exploration in the 1930s brought the influx of humanity experienced during the IGY to the ice-covered continent.
- A new value for total abundance of water in the form of ice on the Antarctic continent. Ninety percent of the planet's ice is found on and around the continent, locking 68% of the world's fresh water in the Southern Hemisphere.
- Improved meteorological predictions by understanding the weather patterns of the Southern Hemisphere.
- Advancements in the theoretical analysis of glaciers.
- Seismology of the Southern Hemisphere.
- The scientific cooperation in Antarctica paved the way for the Antarctic Treaty. The treaty signed on December 1, 1959, created a continent free from nuclear weapons and open to scientific research; the first truly international territory.
- Improved science and math education. Through implied competition among countries, IGY generated a new sense of the importance of math and science to competitive problem-solving.
- Sputnik and satellite measurements. IGY provided the first peaceful use of military equipment and technology to enhance the measurement capability and later communications of people on Earth.
- World Days and Communication. During the IGY, a calendar was arranged to achieve simultaneous observations in most disciplines. During some periods, intensification in observations was considered, and the World Days program was established. There were three classes of special days: Regular World Days (RWD), World Meteorological Intervals (WMI), and Special World Intervals (SWI). RWD and WMI were picked in advance on the calendar. SWI were designed day-to-day and broadcast by the World Warning Agency (AGIWARN).
- World Data Centers. The IGY was predicated on full and open data exchange. The World Data Centers were created to provide equitable access for use by all qualified scientists for public good and for geophysical research as a tool for sustainability.
- World Gravity Map. Over 60,000 observations and additional 150,000 anomaly values results from the various IGY programs. The raw data were prepared for storage and further analysis on punched paper cards for machine analysis. The final values were published as a monograph and supplied to the World Data Centers.
- Postage stamps, films, songs, and pamphlets. Outside of the participating scientists, the new approach included outreach and generational attraction to science at all levels. These creative media and documentary projects contributed to the events during the IGY and continue through today to provide accounts and anecdotes about the progress made by participants in IGY.

Summary

The International Geophysical Year (IGY) was, *and is today*, inspirational and an excellent example of cooperation, collaboration, and communication among the different nations of the world. It's period of time for the event labeled a *Year* was planned as 18 months and was the start of further cooperation, collaboration, and communication among the founders and participants and added members over the years following the IGY. Seven decades of work that included volumes of data collection is now available for further research and study and planning for what may be next. Follow-on achievements are documented, but the success of the IGY must be etched into the progress made from the original works in 1957–1958. IGY was a giant step for mankind, and continued step-by-step knowledge from new measurements is expected.

International Gravity Formula

Hans-Jürgen Götze

Institute of Geosciences, Working group Satellite- and Aerogeophysics, Christian-Albrechts-Universität zu Kiel, Kiel, Germany

Definition

As a first approximation, the Earth is a rotating sphere. As a second approximation, it can be regarded as an equipotential ellipsoid of revolution. According to Moritz (1980), the theory of this equipotential ellipsoid was first given by P. Pizzetti in 1894. It was further elaborated by C. Somigliana in 1929 and served already as the basis for the International Gravity Formula adopted at the General Assembly of the International Union of Geodesy and Geophysics (IUGG) in Stockholm in 1930.

One particular ellipsoid of revolution, also called the “normal Earth” or “normal spheroid,” is the one having the same angular velocity and the same mass as the actual Earth, the potential U_0 on the ellipsoid surface equal to the potential W_0 on the geoid, and the center coincident with the center of mass of the Earth. The Geodetic Reference System 1967 (GRS 67), Geodetic Reference System 1980 (GRS 80), and World Geodetic System 1984 (WGS 84) all are “normal Earth” models.

The normal or theoretical gravity is the gravity effect due to an equipotential ellipsoid of revolution. Approximate formulas are used widely even though we can calculate the exact theoretical gravity analytically. The conventionally used International Gravity Formula is obtained by substituting the parameters of the relevant reference ellipsoid. Helmert's 1901 Gravity Formula and International Gravity Formulas 1930, 1967, and 1980 correspond, respectively, to the Helmert 1906, International 1924, GRS 67, and GRS 80 ellipsoids. For example, the recent 1980 International Gravity Formula is (Moritz 1980):

$$\gamma_{1980} = 9.780327 (1 + 0.0053024 \sin^2 \varphi - 0.0000058 \sin^2 2\varphi) \text{ ms}^{-2}$$

where φ is the geodetic latitude.

The resulting difference between the 1980 International Gravity Formula and the 1930 International Gravity Formula is:

$$\gamma_{1980} - \gamma_{1930} = -16.3 + 13.7 \sin^2 \varphi 10^{-5} \text{ m/s}^2.$$

Similarly, one can compare the 1967 formula to the 1980 formula in use today. The difference between the two is relatively small:

$$\gamma_{1980} - \gamma_{1967} = 0.8316 + 0.0782 \sin^2 \phi \cdot 10^{-5} \text{ m/s}^2.$$

The first term of the International Gravity Formula is the value of gravity at the equator on the ellipsoid surface. Unfortunately, in the 1930s no one really knew what it was. The most reliable estimate at that time was based on absolute gravity measurements made by pendulums at the Geodetic Institute Potsdam in 1906. The Potsdam gravity value served as an absolute datum for worldwide gravity networks from 1909 to 1971. In the 1960s, new measurements across continents were made by precise absolute and relative gravity meters and became the network of IGSN71 still in use today. A mean difference between the Potsdam datum and the IGSN71 reference has been found to be $14 \times 10^{-5} \text{ m/s}^2$ (Woollard 1979).

The theoretical gravity is the gravity effect due to an equipotential ellipsoid of revolution. Approximate formulas are used widely. In fact, the theoretical gravity at any position on, above, or below the ellipsoid surface can be calculated using closed-form expressions also. Such a closed-form expression for the theoretical gravity on the surface of the ellipsoid is given by the formula of Somigliana (Heiskanen and Moritz 1967, p. 76).

The Somigliana–Pizetti formula gives the magnitude of normal gravity on the surface of a geocentric reference ellipsoid:

$$\gamma = \gamma_e \frac{1 + k \sin^2 \phi}{\sqrt{1 - e^2 \sin^2 \phi}}$$

where k is the normal gravity constant (not to be confused with the universal gravitational constant, G), γ_e is the normal gravitational acceleration at the equator, and e^2 is the square of the first numerical eccentricity of the ellipsoid. Importantly, the geocentric latitude N , which is compatible with the GRS80, must be used in the Somigliana formula (Li and Götze 2001; Hackney and Featherstone 2003).

Parameters used to compute the normal gravity using the Somigliana–Pizetti formula are given values for the GRS80 ellipsoid from Moritz (1980) (Table 1).

The recent theoretical formula for gravity as a function of latitude φ using the Somigliana equation provides (Hinze et al. 2013):

$$\begin{aligned} \gamma(\varphi)_{1980} \\ = 9.7803267715 \left[\frac{1 + 0.001931851353 \sin^2 \varphi}{1 - 0.0066943800229 \sin^2 \varphi} \right] \text{ ms}^{-2} \end{aligned}$$

A later refinement of this normal gravity formula is based on WGS 84 (World Geodetic System of 1984) and gives:

$$\begin{aligned} \gamma(\varphi)_{1984} \\ = 9.7803253359 \left[\frac{1 + 0.00193185265241 \sin^2 \varphi}{1 - 0.00669437999013 \sin^2 \varphi} \right] \text{ ms}^{-2} \end{aligned}$$

International Gravity Formula, Table 1 Parameter definition and GRS80 values

A	Ellipsoid semimajor axis	6,378,137 m
B	Ellipsoid semiminor axis	6,356,752.3141 m
γ_e	Equatorial normal gravity	$9.7803267715 \text{ ms}^{-2}$
γ_p	Polar normal gravity	$9.8321863685 \text{ ms}^{-2}$
k	$(b\gamma_p/a\gamma_e) - 1$	0.001931851353
e^2	$(a^2 - b^2)/a^2$	0.00669438002290
f	$(a - b)/a$	0.00335281068118
m	$(\omega^2 a^2 b)/GM$	0.00344978600308
ω	Angular velocity	$7.292115 \times 10^{-5} \text{ rad s}^{-1}$
GM	Geocentric gravitational constant	$3.986005 \times 10^{14} \text{ m}^3 \text{ s}^{-2}$

with: $\gamma_p = 9.8321849378 \text{ ms}^{-2}$ (polar normal gravity). The small differences between the GRS 80 ellipsoid and the current WGS 84 ellipsoid have virtually no practical consequence.

International Polar Year 2007–2008

David J. Carlson
 British Antarctic Survey, IPY International Programme
 Office, Cambridge, UK

Concept

The International Polar Year 2007–2008 (IPY) was an intensive, internationally coordinated scientific research campaign in the Arctic and the Antarctic sponsored by the

International Council for Science (ICSU) and the World Meteorological Organization (WMO). Working together through international projects, IPY researchers examined all aspects of polar regions. IPY highlighted the global importance of polar processes and the urgent need to understand and track extremely rapid changes occurring at high latitudes.

History

By most accounts, the 2007–2008 IPY represented the fourth IPY: 1882–1883, 1932–1933, 1957–1958 (that event grew from a Polar Year into a Geophysical Year – the IGY), and 2007–2008. Although topics and technologies have changed over 125 years, the challenges and difficulties of working in polar regions have not, and the most recent IPY still adheres strongly to the original concept that substantial advances in polar science require, periodically, extraordinary levels of enhanced and focused international cooperation and coordination. With news of sea ice retreat, ice sheet collapse and threats to polar species almost constantly in media headlines, the scientific need for this IPY became obvious.

Scope

The IPY Framework Document (Rapley et al. 2004) specified four goals:

- Make major advances in polar knowledge and understanding.
- Leave a legacy of new or enhanced observational systems, facilities, and infrastructure.
- Inspire a new generation of polar scientists and engineers.
- Elicit keen interest and participation from polar residents, schoolchildren, the general public, and decisionmakers worldwide.

IPY emerged as one of the most ambitious international research efforts in the past 50 years. It engaged the intellectual resources of thousands of scientists – many more than expected and often from nonpolar countries – representing an unprecedented breadth of specialties, from geophysical to biological to social sciences. IPY stimulated international and interdisciplinary collaboration with over 160 endorsed science projects assembled from the ideas of researchers in more than 60 countries. IPY stimulated substantial new funding for polar science – more than US\$ 400 million, which coordinated with and supplemented ongoing polar research and monitoring programs.

Achievements

Major Advances in Polar Knowledge and Understanding

Major IPY-stimulated advances in polar science will emerge in the time period 2009–2015 and beyond, as IPY researchers explore, analyze, evaluate, and share their data sets. Already, we can see increased and more pervasive evidence of change in ice sheets and sea ice; we can see and foresee alteration, migration, and depletion of polar ecosystems; we can see hints of large changes in crucial polar components (sinks and sources) of global carbon cycles; and we can see the early impacts of relentless environmental, economic, and social changes on polar communities. We can predict with confidence, as a major advance in understanding, the increasing recognition of the global importance and impact of polar change.

Infrastructure Legacy

This IPY has done a superior job of observing both polar oceans, through multiple ship voyages and extensive use of buoys, drifters, and autonomous gliders. It has produced, from spaceborne radars, lidars, and gravity sensors, unprecedented coverage and views of the polar ice masses. Four separate multinational teams made difficult traverses across Antarctica, covering some regions for the first time since IGY. Field stations around the Arctic upgraded their capabilities, established new networks, and supported twice and in some cases thrice as many researchers as in previous years.

A New Generation

A new Association of Polar Early Career Scientists (<http://www.apecs.is/>) has brought vibrant and critical energy and ideas to this IPY and to polar science. Now incorporated, internationally endorsed and engaged in all aspects of polar research, and with their own funded Directorate, APECS represents one of IPY's most significant accomplishments. With more than 1,400 members from more than 40 countries, with the ability to do online posters and career development workshops almost anywhere in the world, APECS has clearly succeeded in shaping the future of polar research.

Excite and Stimulate the Public

Through international collaboration and cooperation, by careful cultivation of a global community of enthusiastic volunteers, and by creative use of free technologies, this IPY stimulated active and engaged networks of hundreds of teachers, media officers, journalists, and students. Working with those partners and networks, quarterly Polar Days were organized that engaged more than 500 individual and institutional partners from 50 countries in polar activities. Teacher's workshops, summer schools, polar science weekends, and student expeditions in both hemispheres were conducted. A Polar Resource Book documenting these and many other IPY activities was published. The polar community was

expanded by leaving a legacy of polar information in many languages. This IPY has demonstrated that an effective, energetic, and enthusiastic team working full-time to promote science communication serves as the key partner in a science program's success.

Challenges Ahead

The variety, breadth, and volume of IPY data highlight the fact that international science data infrastructure, largely a legacy of IGY, has for the most part not kept pace with the modern expectations and needs for data access and data preservation. A few national and disciplinary data systems demonstrate admirable capabilities, and new approaches, focused on open access and an information commons approach, such as the Polar Information Commons (<http://www.polarcommons.org/>), may stimulate a data transformation. Identifying and sustaining the essential elements of long-term observation and monitoring systems for polar regions, as those regions undergo rapid change, will represent a severe challenge, one without obvious technical or resource solutions. A more urgent focus on integrated prediction skills and systems will provide improved structure and rationale for maintaining polar observational capabilities. The many science specialties in this IPY, and the wide variety of data, will make the task of synthesis extremely difficult, but they will also stimulate innovative integration processes and result in products of enormous impact and value.

Summary

Often the science community seeks to organize prominent “above and beyond” events, events that transcend business as usual and accelerate scientific processes. Presented as “Experiments” or “Observation Periods” or “Years,” these events share ambitious goals of enhanced research, increased resources, heightened attention and, not coincidentally, re-invigorated recruitment of new researchers. The IPY 2007–2008 succeeded in stimulating international and interdisciplinary cooperation. Through widespread international cooperation and extraordinary enthusiasm, it achieved (in large part) its research, resource, recruitment, and public attention goals, and will produce a positive legacy for participants, for science in general, and for the public.

Göttingen, Germany

Definition

The “International Year of Planet Earth” (IYPE) was a joint initiative by the International Union of Geological Sciences (IUGS) and UNESCO and ran from 2007 to 2009.

Background and Activities

When, in the year 2000, the International Union of Geological Sciences (IUGS) tried to match current scientific knowledge about Planet Earth against the application of such knowledge in daily life, it found a major discrepancy. The Indian Ocean tsunami in 2004 and hurricane Katrina in 2005 only confirmed the existence of that gap; knowledge about natural hazards existed, but it was not applied – or not applied adequately – to protect vulnerable societies from devastation.

Another observation was that fewer and fewer future experts in geoscience had been recruited at universities since the early 1980s, despite the fact that society needs increasing numbers of them to help reduce the impact of such disasters and to assist governments in subsurface management issues. Today, industry needs more geo-experts to find the new earth resources for which the world is desperately searching. Those experts are the same ones that find innovative solutions to reduce the environmental impacts of such necessary resource exploitation.

These observations motivated us to explore how the public and the politicians could be urged to reverse these trends. We chose an international, rather than national, approach and began the long road toward the proclamation of an International Year of Planet Earth (IYPE) under the UN system. IYPE aimed to capture people's imagination with the exciting knowledge about our planet and to see that knowledge used more effectively to make the Earth a safer, healthier, and wealthier place for our children and

grandchildren. That, we believe, can be achieved by building on the knowledge accumulated by the world's 400,000 Earth scientists and is expressed by the IYPE subtitle: *Earth Science for Society*.

Two earlier events served as models. The *International Geophysical Year* (1957–1958) uncovered many facts about our planet, which was then seen for the first time from space. IGY attracted lots of public attention, and many youngsters were inspired to begin their professional careers in Earth sciences. More recently, in 2002, the Germans celebrated their “Jahr der Geowissenschaften” with many public events and with an attractive logo that was later donated to the IYPE. That public exposure resulted in a much higher enrollment of German students in the Earth sciences in subsequent years (Fig. 1). That information fuelled the outreach program of the International Year.

Soon after the inception of IYPE by the International Union of Geological Sciences (IUGS), UNESCO's (former) Earth Science Division joined in, followed by 25 Associate Partners and 11 Founding Partners. To achieve its aims and ambitions, and to collect public and political support for the IYPE, we then approached the United Nations system. That process went through various stages, beginning in UNESCO where the United Republic of Tanzania successfully launched the initiative in UNESCO's Executive Board in April 2005, followed by the General Conference in October. In December 2005, the General Assembly of the United Nations adopted Resolution 192 proclaiming 2008 to be the *International Year of Planet Earth* (United Nations General Assembly 2005).

Shortly afterward, the IYPE Corporation was registered as a not-for-profit 501 (c) (3) Corporation in the USA, consisting of a Board of Directors and a Secretariat based at the Norwegian Geological Survey in Trondheim. Although the International Year was proclaimed by the UN for 2008, its initiators expanded that into a Triennium, starting in early 2007 and closing in June 2010. A Triennium was considered the minimum needed to implement at least part of our ambitious plan.

After the UN proclamation, additional support for the IYPE grew rapidly. By December 2009, 36 International Partners were providing financial and other support. Simultaneously, geoscientific communities in individual countries began to establish IYPE National Committees (Fig. 2) to a total number of 80 National and Regional Committees by the end of the IYPE Triennium. These countries are widely distributed across the globe.

The main activities of the IYPE have been coordinated through Science and Outreach Programs. Both programs essentially operated in a “bottom-up” mode. The Science Program consisted of 10 broad, societal relevant, and multi-disciplinary themes: health, climate, groundwater, ocean, soils, deep Earth, megacities, resources, hazards, and life. Brochures on each of these themes are made available in hard copy in several languages or could be downloaded from IYPE’s Web site: www.yearofplanetearth.org.

The Outreach Program was mainly implemented at national levels. A global launch event was organized at UNESCO headquarters in Paris in February 2008. In addition,

International Year of Planet Earth, Fig. 1 Student enrolment in the Earth sciences in German universities between 1999 and 2007. Note the spike following the successful “Jahr der Geowissenschaften” (2002)

International Year of Planet Earth, Fig. 2 Countries with an established national committee for IYPE (in dark purple). One regional committee for IYPE had been established for East and Southeast Asia

continent-wide launch events took place for Africa (in Arusha, Tanzania) and for Latin America (in Brasilia, Brazil). Finally, a closing event was organized in Lisbon, Portugal, in November 2009. On an international level, brochures and flyers were produced and a global IYPE web-portal developed. Moreover, numerous activities in many countries with IYPE National Committees were monitored and registered.

Education has been an essential element in the International Year of Planet Earth. Many of the national and international activities involved students and focused on participation by secondary and primary school pupils. An example of student involvement was the IYPE global launch event in Paris. In preparation for that event, 18- to 22-year-old students from around the world submitted essays and poems each dealing with one of the International Year's themes. National Committees and the IYPE Secretariat evaluated these and selected the best. Through national and international sponsorship, some 200 winning students from almost every corner of the planet were awarded a free trip to Paris to participate actively in the launch event, including interacting with VIPs on pressing issues concerning Planet Earth. A comparable approach was taken for the Lisbon event, in 2009.

Legacy

The 80 National and Regional IYPE Committees belonged to the most important legacy items of the IYPE. At national levels, these Committees united key players of several, sometimes competing organizations into one joint ambition to raise awareness for the Earth sciences among decision makers and the public. An evaluation among the National Committees proved that this ambition was at least partly accomplished.

Since the onset of the IYPE Triennium in 2007, many thousands of activities all over the globe have taken place. A significant majority of these were related to education. Thousands of schools worldwide paid attention to the International Year of Planet Earth, each in their own languages and cultures. Probably such awareness raising activities under the UN-banner of IYPE have contributed to a strongly increased, more general concern about Planet Earth that we observe today.

Another significant IYPE legacy item was the creation of a Young Earth Science Initiative (YES). This provides a platform for young professionals in the Earth sciences that found its origin at the gathering of young Earth scientists at the Global Launch Event of the IYPE in Paris (2008). From there the YES Initiative expanded, leading to a formal structure, a network of supporting organizations (including IYPE) and a series of international YES Conferences since. By today (2019) YES has some 5000, electronically connected, members (Fig. 3).

At a political level, a flood of public statements were given by leading politicians pleading for implementation of the aims and ambitions of the International Year of Planet Earth: to base decision making more on science and knowledge of the Earth for safer, healthier, and more prosperous societies. National launch events were the most common model for such involvements of decision-makers. There, politicians spoke in support of the IYPE. Such events were often coupled with cultural performances by school kids highlighting the importance of the Earth and sustainable development for future generations.

OneGeology is another major IYPE legacy item. That initiative was positioned under the IYPE banner in 2007. The ambition of that project was to bring together geological data of all nations into a digital database and translate these

International Year of Planet

Earth, Fig. 3 The first international conference for Young Earth Scientists (YES) was held in Beijing, China, in October 2009

into one single computer language. Eventually, that should result into a digital map of the subsurface of the entire world and may eventually provide a third dimension to popular geographical websites, as, e.g., Google Earth. Some 120 national Geological Surveys embarked on this initiative.

Many more legacy items developed during the IYPE Triennium. For example, cross-country geological hiking tours through the Alps: ViaGeoAlpina; an elegant method to assist teachers with simple materials to explain often complex geological processes: EarthLearningIdea; the production of a series of state-of-the art scientific books on each of the ten IYPE Themes, by Springer Verlag; and an UNESCO initiative to measure the conditions of Earth sciences education in Africa and to develop tools to improve these.

Student entries in the Earth sciences have been growing in a considerable number of countries since 2007. Although not all such positive developments may be attributed to the IYPE alone, the International Year of Planet Earth must have contributed at least to some extent to such growth, as that was often positively correlated with high levels of IYPE activities in such nations.

Finally, a Report on the entire IYPE operation had been produced for the United Nations and the IYPE Initiators (IUGS and UNESCO) as a legacy item in 2010.

Perspectives

Spurred by the National and Regional IYPE Committees who considered the IYPE as an excellent opportunity to raise public awareness to use knowledge of the Earth for better decision making and to encourage the youth to go for a professional career in the Earth sciences, and supported by the IYPE Board of Directors, some new initiatives were discussed since 2009. Two major new initiatives developed

with the specific intention to build on the IYPE legacy are described here.

The Earth Science Matters Foundation

The first initiative and offspring from the International Year of Planet Earth has a strong focus on outreach, the most successful and best exposed issue of the IYPE. Originally started in 2010 as the Planet Earth Institute (that was – for legal reasons – never materialized), the Initiative developed under a new name: The Earth Science Matters (ESM) Foundation in 2011. As in the IYPE, both authors of this article have been leading the ESM jointly from the onset. A Board of representatives of supporting organizations (International Partners) was created under the leadership of the second author while the first author operated as the ESM Director. In addition National Focal Points were identified in some 20 nations worldwide. The subtitle of the Earth Science Matters Foundation is “Bringing knowledge of the Earth to Everyone” and several projects dealing with Earth science outreach have been completed since, some of these together with the YES Network. The current ESM Director, Courtney Jermyn, was appointed in the ESM Board meeting in 2016.

GEOPARKS as a Tool

Earth science communication can be difficult, with explanations of complex geodynamic underground or surface processes and the use of scientific terminology often confusing those we want to take with us on a journey to understand and respect our restless planet. While science communication in general can be demanding, it is a prerequisite to convince people, decision-makers, the public at large, by providing up-to-date scientific knowledge on how to maintain and develop our environment in a sustainable way and sometimes to reduce mistrust towards science experts, as well as partly a bias towards industry and tourism (Eder 2019). A wonderful tool

EarthScienceMatters

Bringing knowledge of the Earth to everyone

to approach such challenging goals with respect to Earth Sciences are “Geoparks,” that – as a new international “brand” – are best defined through the criteria and guidelines of the “*UNESCO Global Geoparks*” designation that forms since November 2015 one part of UNESCO’s *International Geoscience and Geoparks Programme (IGGP)*. But even after more than 15 years having established Geoparks around the globe (the “Global Geoparks Network,” GGN, is existing since 2004; the “European Geoparks Network,” EGN, since 2000), it looks like that the ‘old’ prejudice “Geoparks are too popular and unscientific” is still alive. Still many geoscientists do not know sufficiently about Geoparks or do not perceive these as attractive platforms for research, conferences and outreach activities, but – vice versa – many geoscientists involved in the daily work within Geoparks are not familiar with big international scientific undertakings, programs, and conferences.

Global Geoscience Initiative

Another offspring of the IYPE aimed at identifying or designing “world-class” projects for a “Global Geoscience Initiative.” This was explored by an ad hoc group through a brainstorm meeting in July 2009, and the initiative was then presented to Earth scientific audiences at several major geoscientific gatherings around the world. Several topics for such a primarily science-based initiative were submitted and discussed by a broad platform of geoscientists and one topic that was considered both urgent and feasible for implementation emerged: availability and delivery of natural resources for future generations. This initiative was taken up by the International Union of Geological Sciences (IUGS) in 2013, who launched the Resources Future Generations Initiative with the aim of raising awareness of the challenges of sustainable resources supplies (Nickless 2017). Under the auspices of IUGS and organized by Canadian partners a major international Conference (RFG2018) was held on this issue, in June 2018 in Vancouver.

Summary

The International Year of Planet Earth has been particularly successful in its outreach and education programs. As fundraising started to bear fruit quite late in the Triennium, not sufficient funds were available to properly support a (costly) science program. Moreover, several of the 10 science

themes of the IYPE were addressed at national levels through current university curricula and special programs. UN proclamation has been crucial for the success of the IYPE, in particular for national implementation of the aims and ambitions through the 80 National and Regional Committees. These have also been the drivers for developing a new outreach-oriented initiative, the “Earth Science Matters” Foundation.

Inverse Theory, Artificial Neural Networks

William A. Sandham¹ and David J. Hamilton²

¹Scotsig, Glasgow, UK

²Consultraining, Edinburgh, UK

Definition

Geophysical inversion refers to mathematical and statistical techniques for recovering information on subsurface physical properties (magnetic susceptibility, density, electrical

conductivity, etc.) from observed geophysical data and involves the estimation of quantitative models of the Earth.

Artificial neural networks constitute a powerful paradigm which can emulate complex input/output mappings very efficiently.

Introduction

Neural networks have been recognized for many years as a powerful tool for solving complex problems associated with pattern recognition, classification, and generalization and have been used in geophysics in a large variety of different applications. The power of neural networks arises from their ability to emulate complex input/output mappings efficiently.

Comprehensive reviews may be found of all the major geophysical applications of neural networks in a number of excellent tutorial papers (McCormack 1991a, b; Cary and Upham 1992; Fogelman Soulié 1992; Sandham and Leggett 1998; Van der Baan and Jutten 2000; Poulton 2002; Peters et al. 2019). A number of textbooks on the subject have also been published in the last couple of decades (Poulton 2001; Nikravesh et al. 2003; Sandham and Leggett 2003).

In this present entry, the fundamentals of geophysical inversion using neural networks are reviewed. In section “[Geophysical Inversion](#)”, the physics of geophysical inversion are described, together with a short mathematical formulation. In section “[Artificial Neural Networks \(ANNs\)](#)”, the basics of artificial neural networks are discussed. This includes a review of the major types and the training strategies involved and a discussion of issues such as data preprocessing and performance. In particular, the important case of the multilayer perceptron trained with the backpropagation algorithm is considered in some detail. In section “[Geophysical Inversion Using Artificial Neural Networks](#)”, geophysical inversion applications of neural networks are reviewed, including computation of velocity models, split shear wave analysis, impedance inversion, pseudolog prediction, petrophysics, well logging, and potential field inversion.

Geophysical Inversion

Geophysical inversion, or inverse modeling, may be defined as the estimation of quantitative subsurface Earth parameters using measured (observed) geophysical data (Backus and Gilbert 1967, 1968, 1970; Worthington 1987; Lines 1988; Russell 1988, 2019; Bednar et al. 1992; Parker 1994; Treitel and Lines 2001; Gubbins 2004; Ulrych and Sacchi 2005; Russell and Hampson 2006; Jones 2007; Kim and Nakata 2018; Zheng et al. 2019).

Generic definitions of forward and inverse modeling are given in Fig. 1. Mathematically, forward modeling may be described as the transformation $\mathbf{y} = T[\mathbf{x}]$, where $\mathbf{y}$ is the model response, $\mathbf{x}$ is a vector containing the set of subsurface model parameters, and $T[\cdot]$ is some transformation (linear or nonlinear) which describes an observed physical process. For example, in the seismic case, $T[\cdot]$ produces a model response in the form of a synthetic seismogram. Inverse modeling may also be written as $\hat{\mathbf{x}} = T^{-1}[\mathbf{y}']$, where $\hat{\mathbf{x}}$ is now a vector containing the set of estimated subsurface model parameters (the model space), derived from the data vector $\mathbf{y}'$ (the data space). The operator $T^{-1}[\cdot]$ then denotes the inverse transformation from data space to model space.

Unfortunately, analytical expressions for the inverse transformation seldom exist. Numerically, the inverse problem is solved using methods from mathematical optimization theory. A popular iterative solution is to assume an initial guess for a model, compute the model response $\mathbf{y}$, compare it with the observed response $\mathbf{y}'$, and then perturb the model with the hope of achieving a better fit. However, since the underlying physics in most cases is nonlinear, a straightforward inversion is, even under ideal conditions, inherently unstable. One possible solution is to try and linearize the inverse problem. Unfortunately, such methods are notoriously dependent on the choice of the initial guess for the model. Furthermore, the presence of noise in the data makes interpretation of the results additionally difficult and circumspect. A possible alternative is to use stochastic methods like Monte Carlo (MC), simulated annealing (SA), or genetic algorithms

Inverse Theory, Artificial Neural Networks, Fig. 1 (a)

Forward modeling illustrating the derivation of a model response vector $\mathbf{y}$, from the forward transformation $T[\cdot]$ of a subsurface model parameter vector $\mathbf{x}$. (b) Inverse modeling illustrating the derivation of an estimated subsurface model parameter vector $\hat{\mathbf{x}}$ from the inverse transformation $T^{-1}[\cdot]$ of a data vector $\mathbf{y}'$

(GA), all of which provide some insight into the statistical nature of the inverse relationships. Unfortunately, MC is extremely inefficient and computing-intensive in multi-dimensional cases, and both SA and GA need subjective tuning parameters that determine the nature of the stochastic search. Most techniques also involve the assimilation of a priori knowledge during the inversion process, to constrain the result. All these techniques – linear and nonlinear – involve very expensive forward calculations and are necessarily specific to the particular data set used. Also, the solution is generally nonunique.

It is precisely these intractable features of geophysical inversion which has encouraged geophysicists to investigate solutions using artificial neural networks (ANNs).

Artificial Neural Networks (ANNs)

The expeditious pattern recognition and classification abilities of humans are a direct consequence of the human brain having a very large number of highly interconnected biological nerve cells or neurons. The basic anatomy of an individual neuron is shown in Fig. 2.

It consists of a cell body or soma, the output of which is a long, branching fiber called the axon which, on appropriate triggering by the cell, transmits an impulse. A human neuron “fires” when its electrical potential reaches a threshold. The output signal is transmitted by the axon and distributed to other neurons via connecting points termed synapses, located in the tree structure at the end of the axon, which modify the strength of the output signal. The input area of the cell is a set of branching fibers called dendrites. Input signals to the soma are attenuated with an increasing distance from the synapses

Inverse Theory, Artificial Neural Networks, Fig. 2 Biological neural network showing three neurons, each of which consists of a cell body or soma, an output or axon, and a series of inputs or dendrites, with the connecting point between an axon and a dendrite termed the synapse

to the soma. Since the human brain is a very dense neural network with a highly interconnected set of approximately 10^{11} neurons, the axon of each neuron is connected to around 10,000 other cells, resulting in approximately 10^{14} connections or synapses. It is this large number of interconnections, which is the basis for the human brain's immense computational power.

As the name implies, an artificial neural network (ANN), or simply neural network (NN), is a mathematical or computational model that tries to emulate the structure and/or functional aspects of a biological neural network, and as such, represents a technology that is rooted in many disciplines, including neurosciences, mathematics, statistics, physics, computer science, and engineering. ANNs consist of an interconnected group of artificial neurons (programming constructs that mimic the properties of biological neurons), which process information using a connectionist approach to computation. In most cases an ANN is an adaptive system that changes its structure based on external or internal information that flows through the network during a learning phase, realized via suitable training iterations. ANNs may either be used to gain an understanding of biological neural networks or for solving artificial intelligence problems without necessarily creating a model of a real biological system. In the latter case, they may be defined as nonlinear statistical data modeling tools, and can be used to model complex relationships between inputs and outputs or to find patterns in data. Indeed, the power of neural networks arises from their ability to emulate complex input/output mappings efficiently.

There are now some excellent general reviews of ANNs in the literature (Lippmann 1987, 1989; Eberhart and Dobbins 1990; Hush and Horne 1993; Zhang 2000, 2007; Meireles et al. 2003; Wilamowski 2009). A substantial number of books on the subject have also been published over the last number of decades (Aleksander and Morton 1990; Dayhoff 1990; Hertz et al. 1991; McCord Nelson and Illingworth 1991; Nelson and Illingworth 1991; Kosko 1992; Kung 1993; Freeman 1994; Haykin 1994, 1999, 2009; Bishop 1995; Masters 1995; Kasabov 1996; Priddy and Keller 2005). The texts by Haykin (including earlier editions) are probably the most comprehensive and definitive.

The basic building block of an ANN is the (mathematical) perceptron, which was conceived almost 70 years ago by McCulloch and Pitts to mimic the behavior of a biological neuron. The perceptron is also known as an artificial neuron, neurode, processing element/unit (PE/PU), or simply unit. A schematic of a perceptron is shown in Fig. 3a.

This depicts a number of inputs x_{ij} , analogous to the dendrites in a biological neuron, which are modified by corresponding weights w_{ij} , analogous to the synapses. The $w_{ij}x_{ij}$ products are then summed, along with bias b_i , and the result passed through a nonlinear activation function $\varphi(\bullet)$ to produce the final output y_i , analogous to the axon. The

Inverse Theory, Artificial Neural Networks,

Fig. 3 (a) Schematic of an artificial neuron, which modifies inputs x_{ij} by corresponding weights w_{ij} , sums the products along with bias b_i , and passes the result through a nonlinear activation function $\varphi(\cdot)$ to produce the final output y_i . The diagram on the right is a concise way of depicting the neuron. (b) Common activation functions used in artificial neural networks. The range of activation functions is usually $0 \leq \varphi(S_i) \leq 1$, as defined here; however, it is sometimes desirable for the range to be $-1 \leq \varphi(S_i) \leq 1$

activation function transforms the weighted/summed input S_i to a neuron into its activation. Some major types of activation function are shown in Fig. 3b. Historically, the threshold activation function was used. However, this particular function gives only a binary output (i.e., 1 or 0). Also, this particular function is not continuously differentiable, and so the optimum weights were very difficult to estimate. A more popular activation function is the sigmoid, which is continuously differentiable and monotonically increasing.

An ANN is formed by connecting (usually many) PEs together in some fashion. Some of the major ANN paradigms are depicted in Fig. 4.

Once an ANN has been chosen and the number of layers and neurons has been estimated, the various network weights w_{ij} have to be determined, through a network training procedure. Training can either be supervised or unsupervised (see Fig. 5a, b).

Supervised training involves presenting target answers for each input pattern, whereas with unsupervised training, the network adjusts its weights in response to input patterns without target answers, effectively classifying the input patterns into similarity categories. After training has been carried out, network performance is assessed using input patterns which have not been used previously, i.e., as training data (see Fig. 5c). This will indicate whether the network has been overtrained and cannot generalize, and also whether the network has been trapped during training in a local minimum. Performance is dependent on the quality of data, pre-processing involved, training algorithm, network complexity, generalization, and implementation.

One of the most popular ANNs is the so-called multilayer perceptron or MLP (Fig. 4a). This is a feedforward network

consisting of a layer of input distribution nodes, a number of “hidden” layers of perceptrons, and an output layer. In a fully connected version, all distribution nodes and perceptrons are connected to perceptrons in the following layers. The network configuration should allow for an adequate description of the underlying statistical distribution of the spread in the data. Since the number of input nodes and output neurons is usually dictated by the problem, good network design relies on estimating an optimum number of hidden layers and numbers of neurons in each layer. These are usually determined through trial-and-error procedures. A supervised training algorithm called backpropagation (or back-error propagation), popularized in the mid-1980s by Rumelhart and McClelland, is usually used to train a MLP. This iterative, steepest descent algorithm is outlined below.

Step 1: All w_{ij} set to small random values.

Step 2: Input presented together with target outputs t_i .

Step 3: Actual outputs y_i computed.

Step 4: Errors computed for all nodes in a layer,

$$\text{Output layer: } \delta_i = (t_i - y_i)\varphi'(S_i) \text{ hidden layer: } \delta_i = (t_i - y_i)\varphi'(S_i)$$

Step 5: Update weights:

$$w_{ij}(t + 1) = w_{ij}(t) + \eta \delta_i y_j + \alpha [w_{ij}(t) - w_{ij}(t - 1)]$$

Step 6: Return to Step 4 or Step 2.

The weight update in Step 5 includes learning rate (η) and momentum (α) terms to improve the performance of the algorithm. The selection of a learning rate is of critical

Inverse Theory, Artificial Neural Networks, Fig. 4

Some common neural network paradigms. (a) Fully connected multilayer perceptron (MLP) with one hidden layer and two output neurons. (b) Kohonen architecture trained using a self-organizing map (SOM) (unsupervised). (c) Fully connected recurrent network with one output neuron

importance in finding the true global minimum of the error distance. Backpropagation training with too small a learning rate will make agonizingly slow progress. Too large a learning rate will proceed much faster, but may simply produce oscillations between relatively poor solutions. Both of these conditions are generally detectable through experimentation and sampling of results after a fixed number of training epochs. Ideally, the largest learning rate should be used which still converges to the minimum solution. The use of a momentum term can be helpful in speeding algorithm convergence and avoiding local minima. This gives the system a certain amount of inertia since the weight vector will tend to continue moving in the same direction unless opposed by the gradient

term. The momentum term (i) smooths the weight changes and suppresses cross-stitching, i.e., cancels side-to-side oscillations across the error valley; (ii) amplifies the learning rate when all weight changes are all in the same direction, causing a faster convergence; and (iii) enables escape from small local minima on the error surface. Typical values for the learning rate and momentum parameter are $0 < \eta, \alpha < 1$. The momentum term will allow a larger learning rate and thus speed convergence and avoid local minima. On the other hand, a learning rate of 1 with no momentum will be much faster when no problem with local minima or non-convergence is encountered. Other popular training algorithms include quickprop and cascade correlation.

Inverse Theory, Artificial Neural Networks, Fig. 5 The two major network training strategies. (a) Supervised training. (b) Unsupervised training. (c) Post-training performance assessment

A very popular network which uses unsupervised training is Kohonen's self-organizing map or SOM (Fig. 4b). This is a two-layered feedforward network consisting of a layer of input distribution nodes and an output layer usually arranged as a 2-D map which shows the natural relationships among the patterns presented to the network. Essentially, neighboring neurons compete in their activation by means of mutual lateral interactions, and develop adaptively into specific detectors of different input patterns. The unsupervised training algorithm is outlined below.

Step 1: All w_{ij} set to small random values.

Step 2: Input presented.

Step 3: Euclidian distances δ_i between each input node (j) and output node (i), computed:

$$\delta_i = \sum [x_j(t) - w_{ij}(t)]^2$$

Step 4: Select output node i^* with minimum distance.

Step 5: Update weights to node i^* and neighbors:

$$w_{ij}(t + 1) = w_{ij}(t) + \eta(t) \times [x_j(t) - w_{ij}(t)], i \in NE_{i^*}(t)$$

Step 6: Return to Step 2.

Recurrent networks, which involve the inclusion of feedback loops such as the one depicted in Fig. 4c, have a profound impact on the learning capability of the network and its performance.

Many other types of ANN exist, including Hopfield recurrent networks, those based on the adaptive resonance theory of Carpenter and Grossberg, probabilistic, modular and radial basis function ANNs, support vector machines, and more recently, networks including spiking ANNs and wavelet ANNs.

Geophysical Inversion Using Artificial Neural Networks

ANNs offer many advantages to geophysicists for inversion applications, and this has made them an intensely active research area. Indeed, many ANN inversion algorithms are now sufficiently mature and are routinely employed in their respective application area. A number of good reviews of geophysical inversion using ANNs are available in the literature (Raiche 1991; Röth and Tarantola 1991, 1992, 1994; Röth 1993; Roy-Chowdhury et al. 1997; Nunnari et al. 2001; Kappler et al. 2005; Maiti and Tiwari 2010; Russell 2019; Zheng et al. 2019).

The basis of ANN geophysical inversion methods is illustrated in Fig. 6. First, a geophysical model is used to derive many simulated model response vectors $\mathbf{y}^{(i)}$ from a large number N of subsurface model parameter vectors $\mathbf{x}^{(i)}$, where $0 \leq i \leq N$. Next, the response vectors act as input data training sets to an ANN. In supervised training the model parameter vectors are used as the target vectors. Finally, after appropriate training, a new survey data vector $\mathbf{y}'$ is input to the ANN and an estimated subsurface model parameter vector $\hat{\mathbf{x}}$ obtained,

Inverse Theory, Artificial Neural Networks, Fig. 6 The basis of geophysical inversion using ANNs. (a) A geophysical model is used to derive many simulated model response vectors $\mathbf{y}^{(i)}$ from subsurface model parameter vectors $\mathbf{x}^{(i)}$. The response vectors then act as input data training sets to an ANN. In supervised training the model parameter

vectors are also used. (b) After appropriate training, a new survey data vector $\mathbf{y}'$ is input to the ANN and an estimated subsurface model parameter vector $\hat{\mathbf{x}}$ obtained

i.e., geophysical inversion has been achieved. There are many variations of this basic technique.

It is important to emphasize that geophysical inversion using ANNs will only be successful if proper consideration and diligence are provided during the preprocessing and training phases. This is to ensure the prevention of over-training and local minima entrapment (Maiti and Tiwari 2010).

There are many examples in the literature of ANNs being employed across the complete spectrum of geophysical inversion applications, and these publications, many of which are cited below under their respective application domains, should be consulted for further information.

Summary

Geophysical inversion is an essential tool to help geophysicists solve practical environmental, engineering, or exploration problems. This is particularly relevant for situations which require detailed quantitative subsurface information and data. Traditional approaches to inversion are many and varied and include model perturbation/comparison and linearization usually of a nonlinear geophysical model, together with a variety of stochastic methods including Monte Carlo, simulated annealing, and genetic algorithms. These approaches do not perform well in the presence of noise, are very inefficient and computing-intensive, require subjective tuning parameters and a priori knowledge, and/or produce results which are nonunique.

Alternative geophysical inversion methods, based on artificial neural networks (ANNs), have been investigated over the past 15–20 years, to try and overcome the disadvantages of the traditional approaches. These ANN inversion methods have now found considerable success across many different geophysical domains, including seismic attributes, velocity fields, and tomography, to potential field inversion, archaeology, and remote sensing.

With the continuous introduction of improved ANN paradigms and training algorithms, coupled with the ever-increasing power of digital computing hardware [including field-programmable gate arrays (FPGAs)], there is no doubt that ANNs have a very positive future in the exciting and challenging world of geophysical inversion.

Inverse Theory, Global Optimization

Mrinal K. Sen and Paul L. Stoffa

Department of Geological Sciences, UT Institute for Geophysics, Jackson School of Geosciences, The University of Texas at Austin, Austin, TX, USA

Definition

Inversion of geophysical data involves searching for optimal set(s) of earth model parameters that can be used to compute synthetic data that match with observations. The data misfit (or fitness) is often measured by a suitably defined objective function that is generally non-convex. Optimization methods search for a minimum (optimal) value of an objective function. In general, there can be solutions that are locally optimal. *Global optimization* refers to finding the best set of parameters corresponding to the global minimum of an objective function.

Global Optimization

Introduction

The primary goal of geophysics is to determine the properties of the earth's interior from a finite set of remotely sensed measurements from instruments placed on the surface of the earth with perhaps a few in boreholes. The forward problem involves computation of theoretical data for a given set of earth model parameters. Typically, this requires numerical solution of a partial differential equation. The inverse problem whose goal is to estimate earth model parameters from observations is nontrivial due to the fact the data are almost always inadequate, inconsistent, and insufficient (Jackson 1972). In a *model-based inversion* approach, synthetic data are generated for an assumed model and compared with the observed data. This iterative forward modeling procedure is repeated until an acceptable match is obtained between data and synthetics. Thus in this approach, inversion is viewed as *optimization* in which a model is sought that best explains the observations (Fig. 1). Therefore, searching for a model that best explains the field observation the best comprises one of the major tasks of inversion.

Inversion is not restricted to just finding the so-called best-fit model since there can be multiple solutions. In other words, often we have nonunique solutions. Thus, it is very important for a practitioner to have a clear understanding of the forward problem and to impose constraints and restrict the search for an optimal realistic solution within regions that are geologically

Inverse Theory, Global Optimization, Fig. 1 Principle of model-based inversion by optimization

meaningful. This can be addressed by a proper choice of an objective function. One approach to inversion may be termed “exploitation of model space” in which one simply seeks a best-fit model. Another approach may be termed “exploration of model space,” which casts the inverse problem in Bayesian framework (Tarantola 1987) and constructs a posteriori probability density function (PPD) in model space.

Details of geophysical inverse theory with some examples of application can be found in the texts by Menke (1984), Tarantola (1987), Parker (1994), Sen and Stoffa (1995), and Aster et al. (2005). In the following, I will provide a summary of global optimization methods with some examples of application to geophysical inversion.

Method

Background

The essential elements of a model-based inversion algorithm include data, model, forward problem, objective function, and optimization method. We will restrict ourselves to discrete data $\mathbf{d}$ and model $\mathbf{m}$ defined by the following vectors:

$$\begin{aligned} \mathbf{d} &= [d_1 \ d_2 \ d_3 \ \dots \ d_N]^T, \\ \mathbf{m} &= [m_1 \ m_2 \ m_3 \ \dots \ m_M]^T. \end{aligned} \quad (1)$$

In general, $N \neq M$. The forward problem can be represented by the following equation:

$$\mathbf{d}^{\text{syn}} = g(\mathbf{m}), \quad (2)$$

where g is a nonlinear forward modeling operator which operates on the model vector to generate synthetic data vector

$\mathbf{d}^{\text{syn}}$. The next step is to define an objective function that measures a misfit between the observed and synthetic data using a suitably defined norm. The data residual is given by:

$$\Delta \mathbf{d} = \mathbf{d}^{\text{obs}} - \mathbf{d}^{\text{syn}}, \quad (3)$$

and the data misfit norm can be written as:

$$\|\Delta \mathbf{d}\|_p = \left[\sum_{i=1}^N |\Delta d_i|^p \right]^{1/p}, \quad (4)$$

where p is an integer representing the order of the norm. The most commonly used norm is an L_2 norm for which $p = 2$ resulting in a minimization of the mean square error. This corresponds to the popular least squares minimization approach.

To address the issues of stability and nonuniqueness, constraints are incorporated by adding a model norm term, which can be used to impose smoothness, positivity, and bounds. A detailed description of this issue is beyond the scope of this chapter. A fairly general objective function with such constraints using an L_2 norm can be written as:

$$\begin{aligned} F(\mathbf{m}) &= (\mathbf{d}^{\text{obs}} - \mathbf{d}^{\text{syn}})^T \mathbf{W}_d (\mathbf{d}^{\text{obs}} - \mathbf{d}^{\text{syn}}) \\ &\quad + \alpha (\mathbf{m} - \mathbf{m}^{\text{prior}})^T \mathbf{W}_m (\mathbf{m} - \mathbf{m}^{\text{prior}}), \end{aligned} \quad (5)$$

where $\mathbf{W}_d$ and $\mathbf{W}_m$ are the data and model weighting matrices, $\mathbf{m}^{\text{prior}}$ is the prior model, and α is a regularization weight. The misfit function given by Eq. (5) is also called the objective function, cost function, error function, energy function, etc. in different applications.

Optimization

The goal of an optimization algorithm is to search for the minimum of an objective function such as the one defined by Eq. (5). Note that the operator g in Eq. (2) is, in general, a nonlinear operator. Therefore, the objective function (Eq. 5) is expected to be non-convex with multiple peaks and troughs (Fig. 2). In other words, the objective function can have multiple local minima; the minimum of all the local minima is called a “global” minimum (e.g., Gill et al. 1981). In most applications, once an objective function has been defined, the goal is to find the global minimum of the objective function.

Optimization methods vary depending on the method of search for the minimum. They can be broadly classified into two categories: local optimization and global optimization. The local optimization methods generally use calculus-based rules to find an update in their search. In other words, they make use of local gradient and/or curvature of the objective function to compute an update. Most of these methods are deterministic in nature and the success of these methods is

Inverse Theory, Global Optimization, Fig. 2 A hypothetical error function as a function of model (the model is assumed to have only one model parameter) showing several minima. The iterative gradient method will find the global minimum only when starting at position 1. Others will end up in secondary minima of the error function

largely dictated by the choice of the starting model. Only if the starting model is close to the globally optimal model, can we expect to reach the global minimum using local optimization methods. These techniques cannot generate or even use the global information needed to find the global minimum for a function with multiple local minima.

The global optimization methods, on the other hand, are mostly based on stochastic rules and use more global information about the misfit surface to update their current position. The interaction between computer science and optimization has yielded new practical solvers for global optimization problems, called *meta-heuristics*. The structures of meta-heuristics are mainly based on simulating nature and artificial intelligence tools. Meta-heuristics mainly invoke exploration and exploitation search procedures in order to diversify the search all over the search space and intensify the search in some promising areas. Therefore, meta-heuristics cannot easily be entrapped in local minima. However, meta-heuristics are computationally expensive due to their slow convergence. One of the main reasons for their slow convergence is that they may fail to detect promising search directions especially in the vicinity of local minima due to their random constructions.

The convergence of these methods to the globally optimal solution is not guaranteed for all the algorithms. Only for some of the algorithms under certain conditions is convergence to the globally optimal solution statistically guaranteed. Also, with real observational data, it is never possible to know whether the derived solution corresponds to the global

minimum or not. However, our experience indicates that we are able to find many good solutions starting with only poor initial models using global optimization methods (Sen and Stoffa 1995). They are less greedy than the well-known local optimization methods in that during iterative optimization worse solutions are occasionally accepted which allow these algorithms to avoid local minima. There are several variants of global optimization methods; detailed descriptions of some of these approaches as applied to geophysical inversion can be found in Sen and Stoffa (1995). Here I will provide brief descriptions of a few commonly used global optimization methods, namely the *simulated annealing* (SA), *genetic algorithms* (GA), *neighborhood algorithms* (NA), *particle swarm optimization* (PSO), and *trans-dimensional inversion*.

Simulated Annealing Simulated annealing was first proposed by Kirkpatrick et al. (1983). It is analogous to the natural process of crystal annealing when a liquid gradually cools to a solid state. The SA technique starts with an initial model $\mathbf{m}_0$, with an associated error or energy $E(\mathbf{m}_0)$. It draws a new model $\mathbf{m}_{\text{new}}$ from a flat distribution of models within the predefined limits. Note that each model parameter can be bounded by different limits. The associated energy (objective function value) $E(\mathbf{m}_{\text{new}})$ is then computed and compared against $E(\mathbf{m}_0)$. If the energy of the new state is less than the initial state, the new state is considered to be good. In this case, the new model is accepted and replaces the initial model unconditionally. However, if the energy of the new state is larger than the initial state, $\mathbf{m}_{\text{new}}$ is accepted with the probability of $\exp(-(E(\mathbf{m}_{\text{new}}) - E(\mathbf{m}_0))/T)$, where T is a control parameter called annealing temperature that controls if the “bad” model should be carried over to the new model. This completes one iteration. It is the rule of accepting with a probability that makes it possible for SA to be able to jump out of the local minima. The same process is repeated for a large number of times, with the annealing temperature gradually decreasing according to a predefined scheme. Hopefully with a carefully defined cooling schedule, a global minimum can be found. One may choose a linear or a logarithmically decreasing cooling scheme. The tradeoff here is between the computation cost and the accuracy of the result. Fast cooling will fail to produce a crystal (the algorithm gets stuck in a local minimum), and slow cooling takes a long time but may eventually find the global minimum.

To speed up the annealing process without much sacrifice in the solution, a variant of SA, called very fast simulated annealing (VFSA) was proposed by Ingber (1993). VFSA differs from SA in the following ways. The new model is drawn from a temperature-dependent Cauchy-like distribution centered on the current model (Fig. 3). This change has two fundamental effects. First it allows for larger sampling of the model space at the early stages of the inversion when the temperature is high, and much narrower sampling in the

Inverse Theory, Global Optimization, Fig. 3

A flowchart for global optimization by simulated annealing. Note that the VFSA draws models from a Cauchy-like distribution whose shape changes with iteration

model space as the inversion converges when the temperature decreases. Second, each model parameter can have its own cooling schedule and model space-sampling scheme. Therefore, it allows for the individual control for each parameter and the incorporation of a priori information. For many geophysical inversion applications, VFSA has been demonstrated to have excellent performance (Sen and Stoffa 1995).

Genetic Algorithm Genetic algorithms are so named because they emulate the biological processes of evolution and are based on the principle of survival of the fittest (e.g., Goldberg 1989). In a GA, the model parameters are coded in binary form (Fig. 4). The algorithm starts with a randomly chosen population of models called *chromosomes*. The second step is to evaluate the fitness values of these models. Note that unlike our preceding discussion on optimization in which we attempt to minimize an objective function, a GA searches for the maximum of a suitably defined fitness function that measures similarities between the observed and synthetic data. After the selection process, the three genetic processes of selection, crossover, and mutation are performed upon the models in sequence.

In *selection*, models are copied in proportion to their fitness values based on a probability of selection. Thus during this process, models with higher fitness values (lower error values) have higher probability of getting selected.

Crossover acts on the selected pairs of models. This operation picks a crossover site within the paired strings and exchanges, based on a crossover probability, the bits between

the two models to the right of the crossover site (Fig. 4). Thus the crossover process results in two new models (or children).

Mutation, which involves changing a bit at random based on a mutation probability, is applied to the models to maintain diversity.

After execution of these three processes, the new models are compared to the previous generation and accepted based on an update probability (Stoffa and Sen 1991). The procedure is repeated until convergence is reached, i.e., when the fitness of all the models becomes close to one another.

Note that the repeated applications of selection, crossover, mutation, and update do not necessary guarantee convergence to the global maximum of the fitness function. Nonetheless, the algorithm has been found to be successful in many optimization problems including those from Geophysics.

Neighborhood Algorithm (NA) NA was introduced by Sambridge (1999). The principal idea behind this algorithm is to generate a set of models, at each generation, whose sampling density is constructed from all previous models (Sambridge and Mosegaard 2002). In other words, the proposal distribution to draw the models from is updated at each iteration. One other unique feature of the algorithm is that the algorithm involves portioning of the model parameter space into nearest-neighbor or Voronoi cells about each of the models and thus the information in the previous model samples drives the search for new models. At regular intervals, the approximation is updated, and sampling can concentrate in multiple regions.

Inverse Theory, Global Optimization, Fig. 4 Genetic algorithms are based on binary coding of model parameters (a) and then processes of crossover and mutation (b)

Particle Swarm Optimization The particle swarm is an stochastic evolutionary computation technique (Kennedy and Eberhart 1995) used in optimization, which is inspired by observation of social behavior of individuals (called particles) in nature, such as bird flocking and fish schooling. This has been successfully used in many different science and engineering fields including Geophysics (Shaw and Srivastava 2007). PSO defines a swarm of particles (models) in an M-dimensional space. Each particle maintains memory of its previous best position, $\mathbf{p}_i$ and velocity, $\mathbf{v}_i$. At each iteration, a velocity adjustment of the particle is determined jointly by the previous best position occupied by the particle and the best position of the swarm. The new velocity is then used to compute a new position for the particle. The component of the velocity adjustment determined by the individual's previous best position has been termed as

the *cognition*, and the component influenced by the best in the population is the *social* part. The velocity update formula is given by:

$$\begin{aligned} \mathbf{v}_i^k &= \mathbf{v}_i^{k-1} + b \cdot \text{ran}(\cdot) (\mathbf{m}_i^l - \mathbf{m}_i^k) + c \cdot \text{ran}(\cdot) (\mathbf{m}_g - \mathbf{m}_i^k) \\ \mathbf{m}_i^{k+1} &= \mathbf{m}_i^k + a \mathbf{v}_i^k, \end{aligned} \quad (6)$$

where, $\mathbf{m}_i^k$ is the current location, $\mathbf{v}_i^k$ is the current velocity, $\mathbf{m}_i^l$ is the best location so far, $\mathbf{m}_g$ is the best location achieved by the swarm prior to the kth iteration, $\text{ran}(\cdot)$ is a random number generator, and a, b, and c are constants. This algorithm is very intuitive and easy to program.

Trans-dimensional Inversion In most inverse problems, we assume that the number of model parameters is assumed known, which introduces bias in our estimates. In a trans-dimensional inversion, the model dimension is also treated as an unknown. This is generally formulated using a Bayesian framework and sampling is done using a reversible jump Monte Carlo method (RJMCMC, Malinverno 2002), which is a computationally expensive method. Most recently, Sen and Biswas (2017) developed an RJMCMC method that is augmented by large gradient steps resulting in a faster trans-dimensional algorithm. This new approach has also been applied successfully by Biswas and Sen (2017) to a computationally intensive full waveform inversion problem.

Applications

Several applications of global optimization to geophysical data can now be found in the literature. Due to space limitation, I include here only two examples, which are particularly intriguing since both of these applications address the issue of joint inversion of disparate datasets.

Roy et al. (2005) implemented a joint inversion of first arrival travel time and gravity data with application to field data from a geologically complex subduction zone. They employed a layer-based model description, in which interfaces (which may also be called iso-velocity lines) were defined by a summation of arc-tangent functions. Within each layer, the velocity is assumed to vary linearly with depth at each surface location. Because of the nonuniqueness of the gravity inversion, they used prior knowledge to relate velocity to density values. The nonlinear optimization problem was solved by a very fast simulated annealing (VFSA) technique. At each iteration, travel times were generated by the solution of the eikonal equation while the gravity anomalies are computed using a standard formula. The objective function consists of two parts: one measures the misfit in travel time and the other measures the misfit of gravity anomalies. The technique was applied to field data collected over the Ryukyu subduction zone offshore Taiwan during an ocean

Inverse Theory, Global Optimization, Fig. 5 Example of joint inversion of first arrival seismic travel time and gravity data (modified from Roy et al. 2005): the left panel shows the best fit P-wave velocity (top) and density (bottom) models; the right panel shows the travel time (top) and gravity anomaly (bottom) fit

Inverse Theory, Global Optimization, Fig. 6 Joint inversion of time-lapse seismic and well production data obtained by pilot point parameterization and very fast simulated annealing (modified from Jin

et al. 2009): true porosity (top left); inversion result using only well data (top right); inversion result using only seismic data (bottom left); and inversion result using both seismic data and well data (bottom right)

bottom seismometer (OBS) experiment (called TAICRUST) conducted in the year 1995. An example of results from a profile along NS direction is shown in Fig. 5. The left panel in Fig. 5 shows the velocity and density models derived by joint inversion of travel time and gravity data. The fit between observed and synthetic data is shown in the right panel of Fig. 5.

The second application (taken from Jin et al. 2009) is that of joint inversion of flow and seismic data for reservoir parameters. It is a challenging task in that these disparate datasets are sensitive to different physics and model resolutions for the forward problem. To overcome some of these challenges, Jin et al. (2009) developed a global optimization method based on very fast simulated annealing (VFSA) and a pilot-point-based model parameterization scheme. Reservoir simulation was used to create the saturation and pressure distribution with time. The simulation results were converted to seismic properties using an appropriate rock physics model. Seismic modeling was used to create the seismic response. The objective function was defined as a weighted sum of data misfit and model misfit and VFSA was used to

derive optimal model parameters. Results from application to a synthetic dataset are shown in Fig. 6. A comparison of results from using well data alone (top right panel), seismic data alone (bottom left panel), seismic and well data (bottom right) with the true model parameters (top left panel; a 2D porosity slice) shows marked improvement with the use of time-lapse seismic and well production data (Fig. 6).

Summary

Most geophysical inverse problems are nonlinear in nature and require searching for the minimum of an objective function that is often multimodal. Although linearization of the forward problems and use of local optimization methods have been fairly successful in many applications, many complex problems show suboptimal results using these methods. The global optimization methods are not sensitive to the choice of the starting models and make no assumption on the shape of the objective function. These methods, however, require numerous forward model evaluations and are therefore,

computationally expensive. With the advent of cheap fast computers with large memory, applications of these methods are becoming increasingly popular. In some applications, hybrid methods based on local and global optimization (e.g., Chunduru et al. 1997; Porsani et al. 2000) can be designed that can take advantage of both the approaches.

Introduction

The activity of solving inverse problems is all pervading. We perform this activity throughout our life right since birth. As a new born baby the first inverse problem we solve, albeit through pattern recognition, is identification of mother in a group of persons. In this vein, the geophysical inverse problems are just a member of the class of inverse problems encountered and studied in science. Formally, the inverse problem can be defined as an estimation of system parameters together with their uncertainties from the observed system response to a given source excitation. In contrast, the forward problem is defined as computation of response of the system for a given model of its properties and for a given source excitation. Most of the geophysical inverse problems are nonlinear by virtue of the system response being a nonlinear function of system parameters. However, a widely employed class of methodologies solves the nonlinear inverse problems through quasi-linearization whereby the nonlinear problem is recast into a sequence of linear problems that are solved iteratively using linear methodologies. Further, since bulk of the nonlinearity signatures in a geophysical inverse problem arise from geometry of the distribution of physical property, the problem can be recast, in some cases, to a linear problem when the model geometry is considered known. For example, in gravity studies, if the domain of study is divided into small cubes of known volumes and the unknowns are only the density of cubes, the corresponding inverse problem is linear. Similarly, in case of a layered earth model, the problem can be cast into a linear one when the layer thickness is assumed to be known according to some criterion, for example, constant travel time in case of seismics, constant

thickness in DC resistivity, or constant skin depth in case of magnetotellurics (Kunetz 1972; Gupta et al. 1996, 1997). So, there exists an enormous interest in methodologies for solving the linear inverse problems. This article deals with general aspects of linear inverse theory, the description of well- and ill-posed problems, the least square, minimum norm, and generalized inverses of a matrix, the data and parameter resolution matrices, and the ways of handling noise in data. Lastly, the seminal method proposed by Backus and Gilbert (1967, 1968, 1970) for solving linear inverse problems is discussed in some detail. For rigorous readings on inversion theory one can refer the books by Aki and Richards (2002), Indira and Gupta (1998), Lines and Treitel (1984), Menke (1984), Scales et al. (2001), Sneider and Trampert (1999), Tarantola (2005), Tikhonov and Arsenin (1977), Twomey (1977), and Zhdanov (2002), while for numerical aspects of inverse problems one can refer the books by Bjorck (1996), Lawson and Hanson (1995), and Rao and Bhimasankaram (1992) and also the works of Rojas and Sorensen (2002) and Saltelli et al. (2006). For applications and case studies, one can refer Aki and Richards (2002) and Tarantola (2005) for seismological inverse problems, Borcea (2002) for electrical impedance tomography, Habashy and Abubakar (2004) for electromagnetic inversion, Mallat (2009) for signal processing, and Rawlinson et al. (2010) for seismic tomography. For general geophysical applications one can refer to Treitel and Lines (2001) and Oldenburg and Li (2004).

Linear Inverse Problems

The common linear inverse problems can be presented in the form of Fredholm's integral equations of first kind,

$$g(y) = \int_a^b K(x, y)f(x)dx, \quad c < y < d. \quad (1)$$

Here, $K(x, y)$ is the kernel function that transforms the system parameter function, $f(x)$, into the observable function $g(y)$. A special class of linear problems is the convolution problem where the kernel function has the special form $K(y-x)$.

The problem of obtaining a function, $f(t)$, from its Fourier transform function, $F(\omega)$, can be looked upon as an inverse problem as stated below

$$F(\omega) = \int_{-\infty}^{\infty} f(t)e^{-i\omega t} dt. \quad (2)$$

Oldenburg (1976) studied this linear inverse problem using Backus–Gilbert method.

Another example, the gravity anomaly problem can be stated as

$$g_z(\mathbf{r}) = \iiint_V \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} d^3\mathbf{r}'. \quad (3)$$

Here, $\rho(\mathbf{r}')$ is the unknown density distribution and the remaining factor defines the kernel function. The anomaly $g_z(\mathbf{r})$ is a linear function of density $\rho(\mathbf{r}')$. It may be noted that it is a convolution type problem.

Similarly, in DC resistivity method, the apparent resistivity function, $\rho_a(r)$, is linearly related to the resistivity transform function, $T(\lambda)$, through the kernel function as

$$\rho_a(r) = \int_0^{\infty} T(\lambda)J_n(\lambda r)d\lambda. \quad (4)$$

Ghosh (1971a, b) transformed this problem to a convolution problem by transformation of independent variables.

The discrete equivalent of linear problems can be cast in the form of a matrix equation as

$$\mathbf{Ax} = \mathbf{b}. \quad (5)$$

Here, $\mathbf{A}$ is an $m \times n$ matrix, $\mathbf{b}$ is the m -dimensional observation data vector and $\mathbf{x}$ is the n -dimensional parameter variable vector to be determined.

The traditional solution of this problem exists only for the case where $m = n$ and the coefficient matrix is nonsingular so that its exact inverse exists. However, in such special cases also there exist serious problems. Consider the simple example

$$\begin{aligned} x + y &= 2 \\ x + 1.0001y &= 2.0001 \end{aligned}$$

The solution of this problem is $x = y = 1$. However, if the right-hand side vector is an outcome of some observations where accuracy is only up to two decimal places, statement of the problem may become

$$\begin{aligned} x + y &= 2 \\ x + 1.0001y &= 2.00 \end{aligned}$$

The solution will now be $x = 2, y = 0$. Such drastic change in the solution vector for a very small change in data vector is a reflection of the problem being an *unstable* one. Similarly, if our coefficient is an outcome of some computations where the accuracy is only up to two decimal places, assuming the data vector to be error free, the problem becomes

$$\begin{aligned}x + y &= 2 \\x + 1.00y &= 2.0001\end{aligned}$$

In this case we find that the two equations are *inconsistent*.

Lastly, if in the previous case the data is also erroneous, the resulting equations are

$$\begin{aligned}x + y &= 2 \\x + 1.00y &= 2.00\end{aligned}$$

Now there exist infinite solutions and the problem is *nonunique*.

These problems of instability, inconsistency and nonuniqueness invariably crop up while solving inverse problems. If a problem has any one of these features it is termed as an ill-posed problem. Hadamard (1902) formalized the definition of a well-posed problem in terms of the three conditions:

1. The solution exists.
2. The solution is unique.
3. The solution is stable.

Since in applied mathematics one is interested in obtaining the solution, another condition was subsequently added to this list of conditions for a problem to be termed as well posed, that is,

4. The solution is constructible.

A linear or linearized inverse problem, when cast in a matrix form, can be solved as a least square problem. Here, we shall be discussing various ways of solving the matrix equation in its generality. The various classifications of matrix Eq. 5 can be

1. Case when $m > n = k$, is known as strictly overdetermined.
2. Case when $n > m = k$, is known as strictly underdetermined.
3. Case when $m = n = k$, is known as evenly determined.
4. Case when $k < \min(m, n)$ is known as underdetermined.

Here, k is the rank of matrix A .

In any real problem the observed data is, in general, inadequate and inaccurate. As a result the resulting inverse problem is inconsistent, underdetermined, and most of the time unstable. Under such adverse conditions when the exact solution does not exist, the basic task in solving the matrix Eq. 5 pertains to obtaining a solution that meets the desired objectives. Backus (1970, 1996), Backus and Gilbert (1967, 1968, 1970), Jackson (1972, 1979), and others studied these problems and developed methodologies to obtain a unique solution. It is inevitable that in such cases there would be a trade-off between the propagation of data error

to parameter estimation and the parameter resolution. The inevitable nonuniqueness is removed by incorporating the available a priori information about the unknown parameter vector $\mathbf{x}$. The various methods differ in handling the a priori knowledge about data error and model and in controlling the trade-off between error propagation and parameter resolution.

To be able to solve Eq. 5 one designs a matrix A^g , termed as generalized inverse, such that

$$\mathbf{x} = A^g \mathbf{b}. \quad (6)$$

It is obvious that matrix A^g will not possess all the properties of the exact matrix inverse, A^{-1} , which can be defined only for non-singular matrix. For various cases mentioned above, the generalized inverse will possess only a subset of these properties. One of the important properties of exact inverse is $AA^{-1} = A^{-1}A = I$. In case of a matrix A of order $m \times n$, the generalized inverse matrix, A^g , will lead to the product matrices, $S = AA^g$ of order $m \times m$ and $R = A^gA$ of order $n \times n$ and these, in general, will not be identity matrices. The former product matrix S is termed as *data resolution matrix* or *information density matrix*, while the latter product matrix R is known as *parameter resolution matrix*. These product matrices play an important role in the evaluation of quality of solution. Norms of the deviation of matrices S and R from respective Identity matrices provide quantitative measures of quality of information contained in data vector and of the degree of parameter resolution, respectively.

The matrix A^g can be synthesized in several ways for a given type of coefficient matrix A . The important approaches widely employed to solve the Eq. 5 lead to

1. Least square inverse
2. Minimum norm inverse
3. Damped least square (DLS) inverse
4. Rao–Mitra generalized inverse
5. Moore–Penrose generalized inverse based on singular value decomposition (SVD)

All these approaches are briefly presented below followed by Backus–Gilbert method which also provides a solution of the linear inverse problem stated as Eq. 1.

Generalized Inverses

Least Square Inverse

The least square (LS) solution of a strictly overdetermined problem was first proposed by Gauss in 1795. The LS solution exists even for inconsistent system of equations. It is obtained by minimizing the L2 norm of misfit error vector, that is,

$$\left\{ \begin{array}{l} \text{Minimize } \mathbf{e}^T \mathbf{e} = (\mathbf{b} - \mathbf{Ax})^T (\mathbf{b} - \mathbf{Ax}) \\ \text{Solution : } \mathbf{x} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{b} \\ \text{Inverse : } \mathbf{A}^g = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \\ \text{Information density matrix : } \mathbf{S} = \mathbf{AA}^g \\ \quad = \mathbf{A}(\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \neq \mathbf{I}_m \\ \text{Parameter resolution matrix : } \mathbf{R} = \mathbf{A}^g \mathbf{A} \\ \quad = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{A} = \mathbf{I}_n \end{array} \right\} \quad (7)$$

The expressions of matrices $\mathbf{S}$ and $\mathbf{R}$ reveal that the data quality is not optimal while all the parameters are resolved exactly.

Minimum Norm Inverse

The minimum norm (MN) solution of a strictly underdetermined problem is obtained through constrained minimization of the L2 norm of the unknown vector $\mathbf{x}$.

$$\left\{ \begin{array}{l} \text{Minimize } \mathbf{x}^T \mathbf{x} \\ \text{Subject to the constraint } \mathbf{b} - \mathbf{Ax} = \mathbf{0} \\ \text{Solution : } \mathbf{x} = \mathbf{A}^T (\mathbf{AA}^T)^{-1} \mathbf{b} \\ \text{Inverse : } \mathbf{A}^g = \mathbf{A}^T (\mathbf{AA}^T)^{-1} \\ \text{Information density matrix : } \mathbf{S} = \mathbf{AA}^g \\ \quad = \mathbf{AA}^T (\mathbf{AA}^T)^{-1} = \mathbf{I}_m \\ \text{Parameter resolution matrix : } \mathbf{R} = \mathbf{A}^g \mathbf{A} \\ \quad = \mathbf{A}^T (\mathbf{A}^T)^{-1} \mathbf{A} \neq \mathbf{I}_n \end{array} \right\} \quad (8)$$

The expressions of matrices $\mathbf{S}$ and $\mathbf{R}$ suggest that the data quality is optimal while all the parameters are not resolved exactly and there exists linear dependence amongst some components of the parameter vector.

Damped Least Square Inverse

The DLS solution of an overdetermined problem when rank $k < \min(m, n)$ was concurrently developed by Marquardt, Phillips, Tikhonov, and Twomey. It is obtained by minimizing the two objective functions defining norms of error $\mathbf{e}$ and of unknown vector $\mathbf{x}$, subject to the constraint of $\mathbf{x}$ satisfying the matrix Eq. 5.

$$\left\{ \begin{array}{l} \text{Minimize } \mathbf{e}^T \mathbf{e} = (\mathbf{b} - \mathbf{Ax})^T (\mathbf{b} - \mathbf{Ax}) \text{ and } \mathbf{x}^T \mathbf{x} \\ \text{Subject to the constraint } \mathbf{b} - \mathbf{Ax} = \mathbf{0} \\ \text{Solution : } \mathbf{x} = (\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{I})^{-1} \mathbf{A}^T \mathbf{b} \\ \quad = \mathbf{A}^T (\mathbf{AA}^T + \mu^2 \mathbf{I})^{-1} \mathbf{b} \\ \text{Inverse : } \mathbf{A}^g = (\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{I})^{-1} \mathbf{A}^T \\ \quad \text{or } \mathbf{A}^T (\mathbf{AA}^T + \mu^2 \mathbf{I})^{-1} \\ \text{Information density matrix : } \mathbf{S} = \mathbf{AA}^g \neq \mathbf{I}_m \\ \text{Parameter resolution matrix : } \mathbf{R} = \mathbf{A}^g \mathbf{A} \neq \mathbf{I}_n \end{array} \right\} \quad (9)$$

Here, the parameter λ is a control parameter that represents relative weighting given to the two objective functions. The expressions of matrices $\mathbf{S}$ and $\mathbf{R}$ suggest that neither the data quality nor resolution of parameters is optimal.

Weighted Damped Least Square Inverse

To incorporate any available information about the error characteristics of data and/or about smoothness characteristics of parameter vector, the two objective functions optimized in case of DLS inverse, can be redefined in terms of weighting matrices $\mathbf{W}_e$ and $\mathbf{W}_m$. $\mathbf{W}_e$ is the data error covariance matrix and $\mathbf{W}_m$ is the matrix defining smoothness characteristics of the desired model. $\mathbf{W}_m$ can be constructed from the low order differences of parameter vector components.

$$\left\{ \begin{array}{l} \text{Minimize } \mathbf{e}^T \mathbf{W}_e = (\mathbf{b} - \mathbf{Ax})^T \\ \quad \mathbf{W}_e (\mathbf{b} - \mathbf{Ax}) \text{ and } \mathbf{x}^T \mathbf{W}_m \mathbf{x} \\ \text{Subject to the constraint } \mathbf{b} - \mathbf{Ax} = \mathbf{0} \\ \text{Solution : } \mathbf{x} = (\mathbf{A}^T \mathbf{W}_e \mathbf{A} + \lambda^2 \mathbf{W}_m)^{-1} \mathbf{A}^T \mathbf{W}_e \mathbf{b} \text{ or} \\ \quad \mathbf{x} = \mathbf{W}_m^{-1} \mathbf{A}^T (\mathbf{A} \mathbf{W}_m^{-1} \mathbf{A}^T + \lambda^2 \mathbf{W}_e^{-1})^{-1} \mathbf{b} \\ \text{Inverse : } \mathbf{A}^g = (\mathbf{A}^T \mathbf{W}_e \mathbf{A} + \lambda^2 \mathbf{W}_m)^{-1} \mathbf{A}^T \mathbf{W}_e \text{ or} \\ \quad \mathbf{A}^g = \mathbf{W}_m^{-1} \mathbf{A}^T (\mathbf{A} \mathbf{W}_m^{-1} \mathbf{A}^T + \lambda^2 \mathbf{W}_e^{-1})^{-1} \\ \text{Information density matrix : } \mathbf{S} = \mathbf{AA}^g \neq \mathbf{I}_m \\ \text{Parameter resolution matrix : } \mathbf{R} = \mathbf{A}^g \mathbf{A} \neq \mathbf{I}_n \end{array} \right\} \quad (10)$$

All the above inverses can be considered as special cases of the generalized inverse defined by Rao and Mitra (1971) which is discussed next.

Rao–Mitra Inverse

Rao and Mitra (1971) put forth a definition of generalized inverse, $\mathbf{A}^g$, as any matrix that provides a solution of matrix Eq. 5 as

$$\mathbf{x} = \mathbf{A}^g \mathbf{b}. \quad (11)$$

It is evident that this inverse satisfies the relation

$$\mathbf{AA}^g \mathbf{A} = \mathbf{A}. \quad (12)$$

This condition leads to two more properties

$$\begin{aligned} \mathbf{AA}^g &\text{ is idempotent,} \\ \mathbf{A}^g \mathbf{A} &\text{ is idempotent.} \end{aligned}$$

It may be mentioned that idempotent matrices are those for which any power of the matrix is equal to itself.

Rao and Bhimasankaram (1992) presented a suit of algorithms for evaluating the generalized inverse using Gaussian elimination like steps based on elementary row and

column operations that reduce the coefficient matrix to a Hermite canonical form.

An earlier definition of generalized inverse, A^+ , given by Moore (1920) and rediscovered by Penrose (1955), was based on SVD of matrix A . It satisfies the conditions

$$\left\{ \begin{array}{l} AA^+A = bIA \\ A^+AA^+ = A^+ \\ AA^+ \text{ is idempotent} \\ A^+A \text{ is idempotent} \end{array} \right\} \quad (13)$$

Moore–Penrose inverse (MPI) is always unique while Rao–Mitra inverse (RMI) is, in general, not. In fact, MPI is one member of the set of all possible RMIs. To elaborate this point, it may be stated that for a given SVD of matrix A ,

$$A = U\Lambda V^T. \quad (14)$$

Here U and V are the modal matrices of orders $m \times m$ and $n \times n$, respectively and Λ is an $m \times n$ matrix whose leading k diagonal elements correspond to the nonzero singular values and all other elements are zero.

The MPI is given by

$$A^+ = V\Lambda^+U^T \quad (15)$$

Here Λ^+ is the $n \times m$ matrix whose first k diagonal elements correspond to the inverse of nonzero singular values and all other elements are zero.

In contrast, the RMI is given by

$$A^g = V\Lambda^gU^T. \quad (16)$$

Here matrix Λ^g is an $n \times m$ matrix whose leading $k \times k$ submatrix block is diagonal with nonzero diagonal elements corresponding to the inverse of nonzero singular values and all the other submatrices are arbitrary. This freedom of having arbitrary elements outside the main $k \times k$ block leads to the nonuniqueness of MRI. This, in turn, leads to nonunique solutions of matrix Eq. 5, which can be derived from a given solution, $x^{(1)}$, of Eq. 5 as

$$x = x^{(1)} + (A^gA - I)\xi \quad (17)$$

ξ being an arbitrary vector. One possible vector $x^{(1)}$ can be x + the solution obtained using MPI.

Backus–Gilbert Method

Backus and Gilbert (1967, 1968, 1970) studied in detail the problem of synthesizing solutions to a linear inverse

problem expressible as a Fredholm's equation of first kind like Eq. 1. The main feature of this methodology is the possible detailed study of the trade-off between parameter resolution and error propagation. The Backus–Gilbert method (BGM) is briefly described here both for continuous and discrete cases.

Continuous Inverse Problem

The solution of Equation 1 can be represented as

$$f(x) = \int_c^d G(x, y)g(y)dy, \quad a < x < b \quad (18)$$

For Eqs. 1 and 18 to coexist, it is essential that the functions $K(x, y)$ and $G(x, y)$ satisfy the relations

$$\int_a^b G(x, y)K(x, y')dx = \delta(y - y'), \quad (19)$$

and

$$\int_c^d G(x, y)K(x', y)dy = \delta(x - x'). \quad (20)$$

The function $\delta(r-r')$ is the transcendental Dirac-delta function.

Backus and Gilbert brought into focus the infinitely undetermined nature of the real continuous linear inverse problems represented by Eq. 1. They emphasized that from the finite observations, it would never be possible to exactly determine the infinite unknowns constituting the sought model property function $f(x)$. They circumvented the problem by seeking not the exact solution but its approximation as a linear superposition of the observed data values.

Let the finite observation set comprise m values $g_i = g(y_i)$ with $c \leq y_1 \leq y_2 \leq \dots \leq y_{m-1} \leq y_m \leq d$.

Further let the unknown function $f(x)$ need be estimated at the n argument values $a \leq x_1 \leq x_2 \leq \dots \leq x_{n-1} \leq x_n < b$. Now Eqs. 1 and 18 can be rewritten as

$$g_i = g(y_i) = \int_a^b K_i(x)f(x)dx, \quad \forall 1 < i < m \quad (21)$$

and

$$f_j = f(x_j) = \int_c^d G_j(y)g(y)dy, \quad \forall 1 < j < n \quad (22)$$

where

$$K_i(x) = K(x, y_i) \text{ and } G_j(y) = G(x_j, y). \quad (23)$$

Backus and Gilbert sought an approximation of Eq. 22 as

$$f_j \cong \hat{f}_j = f(x_j) = \sum_1^m c_i(x_j) g_i \quad (24) \quad \text{with}$$

Substituting for g_i from Eq. 21, we get

$$\hat{f}_j = \sum_1^m c_i(x_j) \int_a^b K_i(x) f(x) dx$$

For K_i , and f being square integrable, the order of integration and summation can be interchanged and the equation can be rewritten as

$$\hat{f}_j = \int_a^b \left[\sum_1^m c_i(x_j) K_i(x) \right] f(x) dx = \int_a^b A(x, x_j) f(x) dx \quad (25)$$

where

$$A(x, x_j) = \sum_1^m c_i(x_j) K_i(x), \quad (26)$$

is termed by Backus and Gilbert as averaging kernel and is also known in literature as resolving kernel or scanning function.

From Eq. 25, it is evident that for f_j to be exactly estimated, the averaging kernel should be the Dirac-delta function $\delta(x - x_j)$. This equality is, in general, not achievable. In order to make $A(x, x_j)$ as close to $\delta(x - x_j)$ as possible, the coefficients c'_i s are chosen to satisfy a judiciously chosen δ -ness criterion. One such criterion can be

$$q_j = q(x_j) = \int_a^b J(x, x_j) [A(x, x_j) - D(x, x_j)]^2 dx. \quad (27)$$

Several pairs of functions J, D have been used by different workers. Backus and Gilbert used $J(x, x_j) = 12(x - x_j)^2$ and $D(x, x_j) = \delta(x - x_j)$. They interpreted q_j as the half-width or spread of the resolving kernel A . Hence, c'_i s are so chosen that these minimize q_j subject to the condition that A is unimodular, that is,

$$\int_a^b A(x, x_j) dx = 1 \quad (28)$$

Expressing Eqs. 25, 27, and 28 in matrix form, we get

$$\begin{cases} \hat{f}_j = \mathbf{c}^T \mathbf{g} \\ q_j = \mathbf{c}^T \mathbf{M} \mathbf{c} + \mathbf{a}^T \mathbf{c} + b \\ \mathbf{u}^T \mathbf{c} = 1 \end{cases} \quad (29)$$

$$\begin{aligned} M_{ij} &= \int_a^b K_i(x) K_j(x) dx \\ a_i &= -2 \int_a^b K_i(x) J(x, x_j) D(x, x_j) dx \\ b &= \int_a^b D^2(x, x_j) dx \\ u_i &= \int_a^b K_i(x) dx \end{aligned}$$

Using Lagrange's method of undetermined multipliers, the solution of Eq. 29 is found to be

$$\mathbf{c} = \frac{\mathbf{M}^{-1} \mathbf{u}}{\mathbf{u}^T \mathbf{M}^{-1} \mathbf{u}} \quad (30)$$

Substituting these c -values in Eq. 24, one gets the estimate of unknown physical property function f at argument value x_j . All values $f_1, f_2, \dots, f_n$ are obtained by repeating the above steps for each $x_1, x_2, \dots, x_n$.

The quality of solution can be evaluated by analyzing the characteristics of the averaging kernel $A(x, x_j)$, which ideally should be the Dirac-delta function. Hence, the deviation of the center of $A(x, x_j)$ from x_j and the finite range of x over which $A(x, x_j)$ is nonzero may be taken as pointers to the quality of estimation.

The discussion till now was confined to error-free data. However, if the data is erroneous and its error covariance matrix is $\mathbf{E}$, the procedure need to be modified to get a solution. In such cases, the superposition coefficient vector $\mathbf{c}$ is obtained by minimizing besides q_j given by Eq. 27 and the error propagation measure e_j given by

$$e_j = \mathbf{c}^T \mathbf{E} \mathbf{c} \quad (31)$$

The two objective functions are combined into one as

$$r_j = \mathbf{c}^T \mathbf{N} \mathbf{c},$$

where

$$N = \lambda M + (1 - \lambda)E, 0 \leq \lambda \leq 1. \quad (32)$$

The procedure described above can be followed after replacing matrix M by N and the resulting estimate of coefficient vector will then be

$$c = \frac{N^{-1}u}{u^T N^{-1}u}. \quad (33)$$

Equations 21 and 22 make it obvious that for $\lambda = 1$, spread gets minimized but error propagation is uncontrolled while for $\lambda = 0$, the spread is unlimited and error propagation is minimized.

Discrete Inverse Problem

The implementation of BGM for the discrete case represented by Eq. 5 was given by Gupta (1998) where it is shown that, for error-free case, if the unimodularity constraint is not applied the BG estimate is same as the minimum norm estimate. However, when this constraint is applied the BG estimate has an additional correction term.

The solution of matrix Eq. 5 is synthesized as

$$x = A^g b. \quad (34)$$

To synthesize A^g some norm of $(A^g A - I)$ is minimized. In particular, for L2 norm, we can minimize

$$u^T (\{A^g A - I\} (A^T A^{gT} - I)) u.$$

Here $u^T = (1 \ 1 \ \dots \ 1)$. Minimization yields

$$A^g = A^T (A A^T)^{-1}. \quad (35)$$

This will lead to the minimum norm solution x_{min} .

When the unimodularity condition, asking for each row vector of the resolution matrix $R = A^g A = A^T (A A^T)^{-1} A$ to be of unit length, is imposed as constraint, the solution x_{BG} is found to be given as

$$x_{BG} = x_{min} + \frac{u - Ru}{u^T Ru} (u^T m_{min}) \quad (36)$$

Trade-Off Between Resolution and Error Propagation

In Backus–Gilbert (BG) method Eq. 32 demonstrates the trade-off between the two objective functions. For different values of λ one gets different solutions. Hence, it is expected that some value of λ will provide optimal trade-off solution. BG demonstrated in their paper of 1970 that when the values of objective functions q_j and r_j for each λ are plotted against

each other, one gets an L-shaped curve. This curve reveals that for large value of λ , error propagation is uncontrolled and the spread is optimized while for small value of λ , error propagation is optimized and the spread is uncontrolled. The tip of the L-curve provides the optimal value of λ .

In case of DLS method, the same exercise can be carried out to obtain the optimal value of λ . Lot of research has been put in to devise the strategies to find optimal λ values. Most of these works analyze the dependence of solution on λ through eigen analysis. For details, one can refer Calvetti et al. (2000), Hansen (1992), Reichel and Sadok (2008), and Rezghi and Hosseini (2009).

Summary

This article presents salient aspects of linear inverse problems. The LS formulations and the Backus–Gilbert formulation are discussed in brief. The information density and parameter resolution matrices and their importance are discussed. Finally, the methods for finding the optimal multi-objective optimization parameter λ are briefly mentioned. For more details on SVD one can refer to the article by A. Manglik, while for global optimization techniques for nonlinear inverse problems one can refer to the articles by M. K. Sen and by W. Sandham published in this series.

Definition

Monte Carlo method. A computational technique making use of random numbers to solve problems that are either probabilistic or deterministic in nature. Named after the famous Casino in Monaco.

Monte Carlo inversion method. A method for sampling a parameter space of variables representing unknowns, governed by probabilistic rules.

Markov chain Monte Carlo (MCMC). A probabilistic method for generating vectors or parameter variables whose values follow a prescribed density function.

Introduction

Because geophysical observations are made at (or very near) the Earth's surface, all knowledge of the Earth's interior is based on indirect inference. There always exists an inverse problem where models of physical properties are sought at depth that are only indirectly constrained by the available observations made at the surface. Geophysicists have been dealing with such problems for many years and in doing so have made substantial contributions to the understanding of inverse problems.

Pioneering work on linear inverse problems in the 1960s arose out of the need to understand how to use new surface observables from seismology to constrain radial variations in geophysical properties at depth within the Earth. Data were

few in number and attention was focused on the mathematical structure of the inverse problem and the ways in which reliable information could be recovered. This resulted in a series of important papers beginning with Backus and Gilbert (1967, 1968, 1970). Since that time the geosciences, like many other fields, have moved into a data-rich environment with increasing availability of computational power. Considerable progress has been made over 30 years utilizing the class of linear (typically least squares) parameter estimation algorithms, which are common to many areas of the physical sciences (Aster et al. 2005). In many of the inverse problems encountered the dependence of data on models is nonlinear and this must be taken into account for meaningful solutions. Often this is achieved by performing a local linearization and using *Inverse Theory, Linear*. As the mathematical relationship between data and unknowns becomes complex then linearized methods fail because they depend heavily on having a starting model for the iterative process which must be close enough to the solution for convergence.

Over the last 30 years there has been considerable progress in the solution of highly nonlinear inverse problems involving a limited number of parameters so that thorough exploration can be made of the character of models. Many algorithms have been devised, most of which make use of random numbers to make decisions, that is, in how to generate a set of values of the unknowns whose predictions can be compared to the available data. The original description of Monte Carlo methods by Hammersley and Handscomb (1964) is “the branch of experimental mathematics which is concerned with experiments on random numbers.” By this definition all inversion techniques that make use of random numbers are Monte Carlo methods. Many of the *Inverse Theory, Global Optimization* inversion methods fall within the class. The particular approach known as Markov chain Monte Carlo is the primary focus of the present entry.

Nonlinearity and Multimodal Fitness Functions

Figure 1 shows a fitness surface from an inverse problem that arises in the analysis of infrasound array data. (Infrasound arrays are used by the United Nations Comprehensive Test Ban Treaty Organization to monitor international adherence to the nuclear test ban treaty.) The height of the surface represents the degree of agreement between two oscillatory fields. There are just two unknowns in this case, which represent tuning parameters in the infrasound array. The object of the exercise is to best tune the array for sensitivity to incoming atmospheric signals, which means finding the point on the surface where the fitness is maximum. We see a curved rim of local maxima from background to foreground, with a broader valley of low fit to the left of the central maximum (red). The physics of the forward problem, that is, calculating the

oscillatory field corresponding to a pair of tuning parameters, as well as the nature of the data itself result in a complicated 2-D fitness function.

The set of unknowns that gives the best fit (i.e., smallest misfit) to data corresponds to the global maximum of the multimodal function and to find it one must employ *Inverse Theory, Global Optimization* techniques such as model space search. In this example the global maximum (at the red central peak) was efficiently found with the neighborhood algorithm of Sambridge (1999), which utilizes ideas from the field of computational geometry. Optimization techniques based on local *Inverse Theory, Linear* would only be suitable once a trial solution is found within the vicinity of the global peak (shaded red). Adaptive Monte Carlo-based direct search approaches like genetic algorithms, simulated annealing, and the neighborhood algorithm (see “► [Inverse Theory, Global Optimization](#)”) are able to solve this (two unknown parameters) problem relatively easily due to their ability to detect the variation of the fit and concentrate sampling where there is most benefit.

This example demonstrates the complexity of inverse problems in cases where the data are highly oscillatory waveforms, a common situation in fields such as acoustics and seismology, where the dimension of the problem is often much higher.

For the 2-D example in Fig. 1, the objective is to tune a particular instrument for maximum sensitivity, and it is appropriate to seek a global maximum. More generally in inverse problems the fitness landscape would represent the difference between observations and predictions made by a mathematical model. In this case simply finding the best-fit solution is inadequate. One needs to characterize the uncertainty in the

Inverse Theory, Monte Carlo Method, Fig. 1 A multimodal data fit surface arising from the mismatch between two oscillatory fields in the infrasound inversion problem (Kennett et al. 2003)

solution, for example, assess how noise in the data lead to errors and trade-offs in the estimated model. Linearized techniques (see “► [Inverse Theory, Linear](#)”) could be used, but all uncertainty estimates are then based on the assumption of local linearity and do not truly reflect the global nature of the data constraint.

Another issue that often arises in inverse problems is that of nonuniqueness (see “► [Inverse Theory, Singular Value Decomposition](#)”). In this case it is not possible to fully constrain the unknowns from the data. The model is unbounded and so best data fit solutions do not exist, and extra assumptions or independent information must be introduced to achieve a single optimal solution. In linearized inversion some form of regularization is used. An example is damping a solution back to some reference set of values (or model) (Aster et al. 2005). It is well known that in this case the details of the solution depend on the nature of regularization used. In addition, uncertainty estimates produced by linearized theory often reflect the choice of regularization. Typically, the least well-constrained components of the solution require the most regularization and resulting uncertainty estimates are severe underestimates of the real errors (Aster et al. 2005 for an example) potential leading to overconfidence in the results.

Bayesian Inference

An alternative approach to inversion is Bayesian inference. Many textbooks and review papers are available. Discussions within a geophysical context can be found in Tarantola and Valette (1982), Duijndam (1988a, b), Sambridge and Mosegaard (2002), and Mosegaard and Sambridge (2002). In Bayesian inference, all information on the unknowns is represented in terms of probability density functions (PDF). Within this framework it is accepted that all inference is relative. What one learns from the data gets added to what is known prior to collecting the data and represented in terms of an a posteriori PDF. The most commonly used form of Bayes’ rule is given below

$$p(m|d) = kp(d|m)p(m) \quad (1)$$

where $p(m|d)$ is the PDF of the model vector, m , containing the unknowns, given the data vector, d , containing the data; $p(d|m)$ is the likelihood function measuring the probability of the data, d , being observed given the model m ; $p(m)$ is the a priori PDF on the model (which is known or assumed about m before the data are collected), and k is a constant of proportionality. In a Bayesian framework, all information on the unknown variables in the model is represented by the posterior PDF, $p(m|d)$ and one usually sets about trying to generate an ensemble of candidate solutions to the inverse problem

whose density is distributed according to this function. This is termed sampling the posterior PDF.

The posterior PDF is the product of the likelihood and the prior PDF. Only the former contains the data vector, d . The likelihood increases as the model fits the data better relative to the noise in the data. The form of the likelihood depends on the statistical character of the data errors. A simple example is a multidimensional Gaussian function characterized by a mean and a covariance matrix, both of which are usually known or assumed. The prior PDF represents information known about the model before collecting the data represented in a probabilistic manner, and may take a variety of forms. Again a multidimensional Gaussian is the most simple, but rarely is real information in this convenient form. Prior PDFs can be the most controversial component of Bayesian inference as there is always a degree of subjectivity in any choice, and the only way to represent no prior information is to not have a prior PDF. Comparisons of Bayesian and alternate approaches can be found in Malinverno and Parker (2005).

We see then that instead of seeking a single optimal solution, in a Bayesian framework many samples are sought. Assessment of the constraints placed on the model is achieved by examining collective properties. Typically, this is done by plotting the distribution of samples as a function of one or more subsets of unknowns, calculating credible intervals to represent uncertainty and covariance matrices to examine the trade-offs between parameters.

The main task to be carried out is then to generate random samples that follow the multidimensional posterior PDF $p(m|d)$ arising from the inverse problem. MCMC methods are practical tools for dealing with complicated probability distributions. Used correctly they result in (quasi)-independent samples whose density follows any target PDF. They have been the subject of much research in fields from Theoretical Physics to Computational statistics. For summaries, see Smith (1991), Smith and Roberts (1993), and Bernardo and Smith (1994). Below we describe the MCMC method briefly and provide a simple illustrative example.

Markov Chain Monte Carlo

Fixed Dimension Approach

MCMC can be regarded as a combination of random Monte Carlo sampling and a Markov chain random walk strategy around the model space. The aim is to produce an ensemble of models from a probability distribution, that is, the posterior PDF, using only function evaluations. The basic approach was developed from the work of Metropolis et al. (1953), placed in a Bayesian framework by Hastings (1970), and a useful overview is given in Gilks et al. (1996). The practical applications lagged behind theoretical developments as a consequence of the need for many simulations. However,

the increase in computing power over the last 15 years or so has led to a rapid increase in use of this methodology in geophysics and other fields of Earth Sciences (e.g., Mosegaard and Tarantola 1995; Malinverno 2002; Sambridge et al. 2006; Gallagher et al. 2009).

The algorithm is as follows: first we choose an initial model from the prior distribution, and calculate its likelihood. Then we generate a new model by making a random perturbation (Monte Carlo) to the current model. This new model is known as the proposed model and depends only on the values of the current model (Markov chain). The final stage is to decide whether we replace the current model with the proposed model, or stay at the current model and repeat the whole process. This important step is determined from the acceptance criterion, which is defined below

$$\alpha = \min \left\{ 1, \frac{p(m')p(d|m')q(m|m')}{p(m)p(d|m)q(m'|m)} \right\} \quad (2)$$

where m' and m are the proposed and current models, respectively, $q(a|b)$ is the probability of proposing model a , given a current model b , and the other distributions are as defined earlier. The decision to accept or reject a proposed model is made by comparing the value of α (which is always between 0 and 1) to a uniform (between 0 and 1) random number, u . If $u < \alpha$ then we replace the current model with the proposed model, if not we discard the proposed model and stay at the current model. We then continue the sampling process (perturb the new current model and so on) for many iterations.

The choice of the proposal function is not critical to the correctness of the sampler, but does affect the efficiency, performance, and convergence. A typical choice might be a normal distribution, centered on the current model, and then we need to tune the performance through the scale parameter of this distribution (e.g., the variance). If we choose too small a scale parameter, the proposed model will be very similar to the current model, their likelihoods will be similar, and we will almost always accept the proposed model. If we choose too large a scale parameter, the proposed model will tend to be very different to the current model, and lead to large changes in the likelihood, which are more likely to be rejected. In practice, both situations mean that we tend to move slowly around the model space. The proposal functions need then to be tuned for particular problems to achieve a reasonable balance between accepting and rejecting the proposed models. A reasonable rate of acceptance is around 30–40%. Generally, we can choose proposal functions that are symmetrical, so that $q(a|b) = q(b|a)$, so these terms cancel out in the acceptance criterion. Also, if we choose uniform prior distributions, then the prior terms also cancel. The acceptance criterion then reduces to the original Metropolis et al. (1953) algorithm.

After an initial period sampling (known as the burn-in), the current model from each iteration is taken as representing a

sample from the posterior distribution (the sampling chain is then stationary). If the model space has N dimensions, and we are interested in the distribution on one of the parameters, m_i , for example, then formally we need to solve the following integral

$$p(m_i) = \int p(m_i, m_j) dm_j; \quad (3)$$

$$j = 1, \dots, i-1, i+1, \dots, N$$

that is we need to integrate out the variation in all parameters except m_i . This is known as marginalizing and $p(m_i)$ is the marginal probability distribution of m_i . Using the MCMC samples, we can just plot all value of m_i as a histogram as the sampling effectively deals with the integration.

Also, it is straightforward to calculate estimates of the expected (or average) value for any parameter. Formally, we have the expected value for parameter m_i defined as

$$E(m_i) = \int p(m_i) m_i dm_i \quad (4)$$

Using the MCMC samples, we simply average over all the samples accepted for that parameter, that is,

$$E(m_i) = \frac{1}{N_a} \sum_{j=1}^{N_a} m_i^j \quad (5)$$

where N_a is the number of samples accepted (post-burn-in) for model parameter m_i .

Transdimensional Approach

A major issue concerning most inverse problems, and the approaches used to solve them, is how best to balance the twin desires of fitting the observations and avoiding introduction of unjustified complexity in the resulting models. Green (1995) introduced a transdimensional form of MCMC (referred to as Reversible Jump), in which the inversion procedure involves the inference of the model complexity (see also birth–death MCMC, Geyer and Møller 1994). For finite dimension models (with a fixed number of unknowns) this then typically becomes a question of determining the dimension of the model. If we are dealing with two models with dimensions k and k' , then acceptance criterion can be written as

$$\alpha = \min \left\{ 1, \frac{p(k')p(m'|k')p(d|m', k')q(m|m')}{p(k)p(m|k)p(d|m, k)q(m'|m)} \right\} \quad (6)$$

Here we separate the prior on the number of dimension, $p(k)$, from the model parameter prior, $p(m|k)$. The proposal function $q()$ becomes more complex as we now want to

propose models with different dimensions. Moreover, we need to allow for the transformation from one model to another to ensure that theoretical probability requirements are maintained. In dealing with a situation where we are simply increasing or decreasing the number of parameters, we can write

$$\alpha = \min \left\{ 1, \frac{p(k')p(m'|k')p(d|m',k')g(u^k)}{p(k)p(m|k)p(d|m,k)g(u^k)} |J| \right\} \quad (7)$$

Here u^k and u^k are vectors of random numbers of length r' and r , respectively, and used to transform from one model to another, such that $r + k = r' + k'$, and $g(\cdot)$ is the probability distribution used to generate these random numbers. The term

$|J|$ is the Jacobian, and allows for the transformation between the two models, that is,

$$|J| = \frac{\partial(m', u^k)}{\partial(m, u^k)} \quad (8)$$

The last equation for α is actually a general form for the acceptance criterion, although for fixed-dimensional problems the Jacobian is generally 1, and the proposal functions are of the form as described earlier. The details of the reversible jump acceptance criterion are discussed in more detail by Green (2003), Malinverno (2002), and Sambridge et al. (2006) and examples of the implementation algorithms for variable dimension problems are given in Jasra et al. (2006), Bodin and Sambridge (2009), Charvin et al. (2009), and Hopcroft et al. (2009). One important characteristic of the

Inverse Theory, Monte Carlo Method, Fig. 2 (a) Initial 5,000 iterations for sampling of two parameters for the linear regression problem. (b) Post-burn-in iterations for parameter m_1 . (c) The green points show the post-burn-in sampling, and the contours are the log likelihood function. The blue cross is the best solution (equivalent to the analytical

maximum likelihood or least squares solution). (d) Marginal distribution for parameter m_0 . The histogram is constructed from the post-burn-in accepted samples, and the curve is the analytical solution for the marginal distribution. The two vertical bars mark the upper and lower bounds on the 95% credible interval. (e) As (d) but for parameter m_1

Bayesian transdimensional formulation is that it is naturally parsimonious. For two models that fit the data equally well, it will tend to favor simpler models over complex ones as a consequence of the posterior probability effectively being penalized through the addition of more terms to the prior distribution.

A Simple Example

To demonstrate MCMC in action, we choose a simple two parameter linear regression problem, that is,

$$y_i = m_0 + m_1 x_i + \varepsilon_i, \quad i = 1, \dots, N \quad (9)$$

where m_0 and m_1 are the model parameters, y is an observed/measured value, and ε is the data error. In a Bayesian formulation, this problem has an analytical solution for a uniform prior on the model parameters, assuming the data error is known (Lee 1989, p. 180). We chose $m_0 = m_1 = 1$ and generated 100 synthetic data (y) for random values of x between 0 and 100, and added noise ($\varepsilon = 0.5$). We used Gaussian proposal distributions, with different scale parameters ($\sigma_{m_0} = 0.01$, and $\sigma_{m_1} = 0.001$). In Fig. 2 we show the sampling for the two parameters, starting from a randomly selected model. Figure 2a shows that the sampler has not reached the stationary state until at least 1,500–2,000 iterations. Figure 2b shows the sampling for parameter m_1 for later iterations which is clearly stationary. The sampling resembles a white noise spectrum about the mean (or expected) value, lacking any internal structure as a function of iteration. It is also clear that the sampler manages to move toward the upper and lower extreme values of the parameter range (determined by the posterior PDF and the proposal function scale parameter). These are diagnostic (but qualitative) characteristics of stationarity.

Figure 2c shows the 2-D distribution of samples of the post-burn-in accepted samples (here we thinned the chain taking every 100th sample), compared to the log likelihood function (which is proportional to the log of the posterior distribution as we use uniform priors). The density of the sampling increases around the high likelihood values, but there are still some samples from the lower likelihood regions. Figure 2d, e shows the marginal distributions for the two parameters as a frequency histogram, and also the analytical solutions (scaled to the same peak height). These are constructed simply by taking all the accepted values for a given model parameter, as the sampler effectively integrates out the other parameters. Also shown are the 95% credible interval ranges for each parameter. These are constructed by sorting all the samples for a given parameter in ascending order, and finding the indices for the credible values such that 2.5% of the samples are less than the lower credible value, and 2.5% of the values are greater than the upper credible value.

Again, we can see that the sampler has managed to distribute itself across the distribution according to the posterior probability and these histograms are good representations of the marginal distributions.

Summary

Monte Carlo sampling, relying on random numbers, has been used in geophysics for over 40 years, although the increase in computing power has seen a commensurate increase in applications in the last 15 years or so. This approach avoids the use of gradients, is robust to local minima, and so is suitable for nonlinear inverse problems which often have complex misfit (or fitness) surfaces in high dimensions. MCMC, particularly when used in a Bayesian formulation, provides a means of sampling a model space according to the (unknown) posterior distribution for the model parameters. Transdimensional (or reversible jump) Markov chain Monte Carlo generalizes this approach to allow models of different dimensions to be considered, and provides a means of choosing between models of differing complexity. Quantifying the posterior distribution with MCMC is then a solution to the inverse problem and various types of inference can be made from this distribution (e.g., expected values, marginal distributions, credible intervals) to characterize the model space.

Inverse Theory, Singular Value Decomposition

Ajay Manglik

National Geophysical Research Institute (Council of Scientific and Industrial Research),
Hyderabad, India

Definition

Condition number Ratio of the largest singular value to the smallest singular value of a matrix. For a singular matrix, it is infinite, and it is very large for an ill-conditioned matrix.

Description

Linear geophysical inverse theory (Inverse Theory, Linear) deals with solving a system of linear equations, represented in matrix form as

$$\mathbf{A}\mathbf{x} = \mathbf{b}, \quad (1)$$

where $\mathbf{A}$ is a $m \times n$ Jacobean matrix, $\mathbf{x}$ a $n \times 1$ column vector of perturbations in unknown model parameters with respect to a reference model, and $\mathbf{b}$ the corresponding $m \times 1$ column vector of perturbations in observed responses. For a full rank square matrix ($m = n = p$: the rank of matrix $\mathbf{A}$), it is easy to find a unique inverse $\mathbf{A}^{-1}$ and estimate the model parameters as $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$. However, geophysical inverse problems (Tarantola 1987) mostly deal with inversion of rectangular matrix $\mathbf{A}$ wherein m is either greater than n (overdetermined system representing more number of observations than the unknown parameters, also known as least squares solution) (Lawson and Hanson 1974; Lines and Treitel 1984) or less than n (underdetermined system representing less number of observations compared to the unknown parameters, also called minimum norm solution). For many geophysical problems, the rank p of the matrix is less than m and n . In such situations, linear geophysical inverse theory aims at finding out a pseudo-inverse $\mathbf{A}^{-}$ of $\mathbf{A}$ such that

$$\hat{\mathbf{x}} = \mathbf{A}^{-}\mathbf{b}, \quad (2)$$

where $\hat{\mathbf{x}}$ represents column vector of the estimated model parameters. Moore (1920) and Penrose (1955), using a spectral decomposition form of matrix $\mathbf{A}$, showed that there exists a unique pseudo-inverse $\mathbf{A}^{-}$ of the matrix $\mathbf{A}$ such that (1) $\mathbf{A}\mathbf{A}^{-}\mathbf{A} = \mathbf{A}$, (2) $\mathbf{A}^{-}\mathbf{A}\mathbf{A}^{-} = \mathbf{A}^{-}$,

(3) $(\mathbf{A}\mathbf{A}^-)^T = \mathbf{A}\mathbf{A}^-$, and (4) $(\mathbf{A}^-\mathbf{A})^T = \mathbf{A}^-\mathbf{A}$, where superscript T denotes the transpose of matrix. Further details can be found in Inverse Theory, Linear.

Singular value decomposition (SVD) is a powerful tool to invert matrices that are either singular or numerically very close to singular (ill-conditioned system). Standard matrix equation solvers can fail in such situations. The advantage of SVD is that one need not a priori know the nature of the problem, that is, whether it is overdetermined, under-determined, or partially determined. SVD is very general in the sense that it can be applied to any arbitrary size matrix. The technique was discovered independently by Beltrami in 1873 and Jordan in 1874 as a tool to solve square matrices and was extended to rectangular matrices by Eckart and Young in the 1930s (Stewart 1993). Its use as a computational tool dates back to the 1960s (Golub and Kahan 1965; Golub and Reinsch 1970). Golub and van Loan (1996) demonstrated its usefulness and feasibility in a wide variety of applications.

Following SVD, a matrix $\mathbf{A}$ of size $m \times n$ is factorized in the form

$$\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{V}^T, \quad (3)$$

where $\mathbf{U}$ is a $m \times m$ unitary matrix, $\mathbf{\Lambda}$ is a $m \times n$ diagonal matrix, and $\mathbf{V}$ is a $n \times n$ unitary matrix. The columns of $\mathbf{V}$ form a set of orthonormal vectors called parameter eigenvectors, and the columns of $\mathbf{U}$ form a set of orthonormal basis vectors called data eigenvectors. For a special case of $m = n$, the matrix $\mathbf{\Lambda}$ has the form

$$\mathbf{\Lambda} = \begin{bmatrix} \sigma_1 & 0 & \cdots & 0 \\ 0 & \sigma_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \sigma_n \end{bmatrix}, \quad (4)$$

where $\sigma_1, \dots, \sigma_n$ are called the singular values of matrix $\mathbf{A}$. The number of non-zero singular values is equal to the rank of $\mathbf{A}$. In the SVD representation, the singular values are arranged in the order of decreasing amplitude, that is,

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n. \quad (5)$$

For a real matrix, the columns of matrices $\mathbf{U}$ and $\mathbf{V}$ are orthogonal, that is, $\mathbf{U}^T\mathbf{U} = \mathbf{I}$ and $\mathbf{V}^T\mathbf{V} = \mathbf{I}$, where $\mathbf{I}$ is the identity matrix and T is transpose of matrix. For complex matrices transpose is replaced by complex conjugate.

Inverse of $\mathbf{A}$

The expression for the inverse of $\mathbf{A}$ can be obtained by first substituting Eq. 3 into Eq. 1 to get

$$\mathbf{U}\mathbf{A}\mathbf{V}^T\mathbf{x} = \mathbf{b}, \quad (6)$$

and then applying the following orthogonal transformation

$$\mathbf{b} = \mathbf{U}\mathbf{b}'; \quad \mathbf{x} = \mathbf{V}\mathbf{x}', \quad (7)$$

and multiplying Eq. 6 by $\mathbf{U}^T$, which gives

$$\mathbf{\Lambda}\mathbf{x}' = \mathbf{b}'. \quad (8)$$

Since $\mathbf{\Lambda}$ is a diagonal matrix, we can easily get

$$\mathbf{x}' = \mathbf{\Lambda}^{-1}\mathbf{b}'. \quad (9)$$

From Eq. 7 and Eq. 9, and orthogonality property of data and parameter eigenvectors, we get

$$\mathbf{x} = \mathbf{V}\mathbf{\Lambda}^{-1}\mathbf{U}^T\mathbf{b}, \quad (10)$$

or the inverse of $\mathbf{A}$ can be written as

$$\mathbf{A}^{-1} = \mathbf{V}\mathbf{\Lambda}^{-1}\mathbf{U}^T. \quad (11)$$

Rank-Deficient Matrix and Its Inverse

The advantages of above spectral decomposition can be seen in the case of $\mathbf{A}$ being a singular matrix. Let us assume that only p of n singular values of $\mathbf{A}$ are non-zero. In this case, the data and parameter eigenvectors can be split into two subspaces representing non-zero eigen-space and null-space, respectively, that is,

$$\mathbf{\Lambda} = \begin{bmatrix} \mathbf{\Lambda}_p & 0 \\ 0 & 0 \end{bmatrix}; \mathbf{U} = [\mathbf{U}_p, \mathbf{U}_0]; \mathbf{V} = [\mathbf{V}_p, \mathbf{V}_0], \quad (12)$$

then

$$\mathbf{A} = [\mathbf{U}_p, \mathbf{U}_0] \begin{bmatrix} \mathbf{\Lambda}_p & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{V}_p \\ \mathbf{V}_0 \end{bmatrix}^T, \quad (13)$$

which gives

$$\mathbf{A} = \mathbf{U}_p\mathbf{\Lambda}_p\mathbf{V}_p^T. \quad (14)$$

This indicates that matrix $\mathbf{A}$ can be reconstructed only from non-zero singular values and corresponding vector spaces. An inverse of a rank-deficient matrix can be written as:

$$\mathbf{A}^- = \mathbf{V}_p\mathbf{\Lambda}_p^{-1}\mathbf{U}_p^T, \quad (15)$$

by substituting Eq. 12 into Eq. 11.

Ill-Condition Matrix

Equation 15 assumes that the singular values of the system are either zero or positive scalars. If some of the singular values

are very small, then it is easy to see that the inverse of such values can be very large and, in the case of error in data, can lead to unstable solutions. Stability of the matrix inverse can be defined in terms of ratio of largest to smallest singular value, also called the condition number

$$\eta = \frac{\sigma_1}{\sigma_{\min}}. \quad (16)$$

The matrix is ill-conditioned if the condition number is very large. In such situations, the system can be stabilized by specifying a cutoff threshold η_0 for the condition number and ignoring all singular values that lead to the condition number larger than this threshold. Let there be p non-zero singular values arranged in decreasing order of their amplitudes of which only the first q singular values have the condition number smaller than η_0 . Then $(q + 1, \dots, p)$ singular values can be reset to zero thus reducing the rank of the matrix to q . This can be understood as ignoring finer details of the parameter space, which are associated with small singular values. Geophysical inverse problems normally fall under this category.

For least squares inverse problems, where an inverse of $\mathbf{A}$ is given by the expression

$$\mathbf{A}^- = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T, \quad (17)$$

Marquardt (1963) suggested that an ill-conditioned matrix $\mathbf{A}^T \mathbf{A}$ may be stabilized by adding an arbitrary damping factor λ to its diagonal elements, that is,

$$\mathbf{A}^- = (\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{I})^{-1} \mathbf{A}^T. \quad (18)$$

In terms of singular value decomposition, it amounts to boosting the small singular values of the matrix $\mathbf{A}^T \mathbf{A}$. This can be shown by expressing Eq. 18 in terms of singular values decomposition of the matrix $\mathbf{A}$, which gives

$$\mathbf{A}^- = \mathbf{V} \text{diag}\left(\frac{\sigma}{\sigma^2 + \lambda^2}\right) \mathbf{U}^T, \quad (19)$$

where $\text{diag}(\dots)$ represents the elements of a diagonal matrix. Here, it can be seen that adding λ to small singular values stabilizes the inverse.

Sensitivity to Errors in Data

Field observations normally contain noise superimposed on the actual response. If we assume a noise vector $\boldsymbol{\varepsilon}$, then we observe $\mathbf{b} + \boldsymbol{\varepsilon}$ instead of $\mathbf{b}$. This leads to an error $\delta \mathbf{x}$ in the estimated model parameters. Therefore, for noisy data Eq. 1 may be written as:

$$\mathbf{A}(\mathbf{x} + \delta \mathbf{x}) = \mathbf{b} + \boldsymbol{\varepsilon}. \quad (20)$$

Substituting from Eq. 1, we get

$$\mathbf{A} \delta \mathbf{x} = \boldsymbol{\varepsilon}. \quad (21)$$

Expressing matrix $\mathbf{A}$ in spectral form and applying orthogonal transformation $\delta \mathbf{x}' = \mathbf{V} \delta \mathbf{x}$ and $\boldsymbol{\varepsilon}' = \mathbf{U} \boldsymbol{\varepsilon}$, Eq. 21 gives

$$\delta \mathbf{x}' = \boldsymbol{\Lambda}^{-1} \boldsymbol{\varepsilon}'. \quad (22)$$

This shows that in the case of small singular values, small error in data yields large error in estimated model parameters. This problem of instability of estimated model parameters can be overcome by either truncating the small singular values or boosting these by adding a Marquardt damping factor, as discussed in the previous section. Such treatment nevertheless results in loss of finer details of the model parameters.

Resolution Matrices

In linear inverse theory, the concepts of parameter resolution and data information density analyses are used to analyze the resolution of estimated model parameters and the regions of data contributing maximum to these model estimates. These resolution matrices can be expressed in terms of data and parameter eigenvectors. Parameter resolution matrix for a rank-deficient system can be obtained by substituting Eqs. 1, 14, and 15 into Eq. 2, which gives

$$\mathbf{R} = \mathbf{V}_p \mathbf{V}_p^T. \quad (23)$$

For a well-resolved system, $\mathbf{R}$ is an identity matrix $\mathbf{I}$. For a rank-deficient system, this matrix provides information about the equivalence of various model parameters.

Similarly, data information density matrix can be written as

$$\mathcal{J} = \mathbf{U}_p \mathbf{U}_p^T, \quad (24)$$

by substituting Eqs. 2, 14, and 15 into Eq. 1.

Jupp and Vozoff (1975) provided an elegant description of the concepts of stability of solution and resolution of model parameters for geophysical data contaminated by noise, and Vozoff and Jupp (1975) showed its application to direct current (DC) electrical resistivity and magnetotelluric (MT) data interpretation.

Example

The following example demonstrates the use of SVD for an overdetermined system and ill-conditioned matrix

$$\mathbf{A} = \begin{bmatrix} 3.0 & 1.0 & 2.9999 \\ 1.01 & 2.9 & 0.9999 \\ 0.5 & 2.0 & 0.5 \\ 0.3 & 0.31 & 0.29 \end{bmatrix}, \quad (25)$$

which has rank $p = 3$. It is decomposed into U , Λ , and V with three non-zero singular values as 5.2573, 2.5613, 0.0078, and

$$U = \begin{bmatrix} -0.7700 & 0.6311 & -0.0932 & 0.0115 \\ -0.5380 & -0.6086 & 0.2595 & -0.5224 \\ -0.3285 & -0.4809 & -0.4604 & 0.6699 \\ -0.0988 & -0.0056 & 0.8438 & 0.5275 \end{bmatrix},$$

$$V = \begin{bmatrix} -0.5796 & 0.4047 & 0.7073 \\ -0.5740 & -0.8188 & -0.0019 \\ -0.5784 & 0.4071 & -0.7069 \end{bmatrix}. \quad (26)$$

First three columns of U form matrix U_p whereas V_p is equal to V . Following Eq. 15, the pseudo-inverse of A is obtained as

$$A^+ = \begin{bmatrix} -8.2480 & 23.4520 & -41.7228 & 76.3959 \\ -0.0952 & 0.1905 & 0.3010 & -0.1915 \\ 8.6133 & -23.5143 & 41.6213 & -76.3367 \end{bmatrix}, \quad (27)$$

with the resolution matrix $\mathfrak{R}$ as the identity matrix I .

In this example, third singular value is small having the condition number of 672.89. In order to stabilize the solution, we can reset this singular value to zero (new rank = 2). Thus, the data and parameter eigenvectors become

$$U_p = \begin{bmatrix} -0.7700 & 0.6311 \\ -0.5380 & -0.6086 \\ -0.3285 & -0.4809 \\ -0.0988 & -0.0056 \end{bmatrix} \text{ and} \quad (28)$$

$$V_p = \begin{bmatrix} -0.5796 & 0.4047 \\ -0.5740 & -0.8188 \\ -0.5784 & 0.4071 \end{bmatrix},$$

yielding the pseudo-inverse as

$$A^+ = \begin{bmatrix} 0.1846 & -0.0368 & -0.0398 & 0.0100 \\ -0.1177 & 0.2533 & 0.1896 & 0.0126 \\ 0.1850 & -0.0375 & -0.0403 & 0.0100 \end{bmatrix}, \quad (29)$$

and the resolution matrix $\mathfrak{R}$ as

$$\mathfrak{R} = \begin{bmatrix} 0.4997 & 0.0013 & 0.5 \\ 0.0013 & 1.0 & -0.0013 \\ 0.5 & -0.0013 & 0.5003 \end{bmatrix}. \quad (30)$$

It can be seen that stabilizing of the inverse of the matrix comes at the cost of compromising on the resolution of model parameters. Here, first and third parameters are coupled when the rank of the matrix is reduced.

Summary

SVD is a powerful tool to solve geophysical linear inverse problems which often deal with rank-deficient singular matrices. The advantage of SVD is that one need not a priori know the nature of the problem, i.e., whether it is overdetermined, under-determined, or partially determined. It is very general in the sense that it can be applied to any arbitrary size matrix.

Isostasy

A. B. Watts

Department of Earth Sciences, University of Oxford, Oxford, UK

Synonyms

Isostacy – (Dutton 1882).

Definition

Isostasy – a principle or general law (Heiskanen 1931). *Isostasy considers there is a certain surface within the Earth, known as the depth of compensation, on which the vertical stresses due to an overlying column of rock are equal (isos = Greek ἴσος “equal,” stasis = Greek στάσις “a standing still”). Isostasy implies a state of hydrostatic equilibrium such that the Earth’s crust and mantle float on their substrate and light regions have a greater elevation than dense regions.*

Isostatic equilibrium – an idealized state that the outermost layers of the Earth tend toward following their disturbance by the addition or removal of loads associated, for example, with the waxing and waning of ice sheets, the growth and decay of volcanoes and deposition, sliding and slumping of sediments.

Local isostasy – a hypothesis that the outermost layers of the Earth are weak such that the deformation caused by loading and unloading is localized, intense, and may involve faulting.

Regional (or flexural) isostasy – a hypothesis that the outermost layers of the Earth have an intrinsic strength such that they resist the deformation associated with loading and unloading and bend (or flex) over a broad area rather than break.

Thermal isostasy – a hypothesis that the outermost layers of the Earth form a cooling thermal boundary layer and that regional differences in topography are controlled by differences in the temperature structure such that hot regions have a greater elevation than cold regions.

Historical Background

Isostasy is a principle that has played a major role in our understanding of the structure, morphology, and tectonic evolution of Earth’s outermost layers. The term was first coined by Dutton (1889), but there is evidence (Delaney 1940; Vai

2006) that the equilibrium state of the Earth’s crust was being considered much earlier by, for example, the Italian scientists Leonardo da Vinci (1452–1519) who pondered the occurrence of marine fossils at high elevations in mountain ranges and by Luigi Fernando Marseli (1658–1730) who was puzzled about the juxtaposition of ocean deeps and mountains. J. F. W. Herschel (1792–1871) was one of the first to link subsidence in one area to uplift in another by some sort of subcrustal mantle flow and both C. Lyell (1797–1875) and C. Babbage (1790–1871) through observations at the Temple of Serapis appreciated that the same area of the crust could experience both subsidence and uplift.

The break through that led to the formulation of the principle of isostasy came following George Everest’s pioneering geodetic work in South Africa and India. Airy (1855) and then Pratt (1855) used Everest’s deflection of the vertical data in northern India to address the question of how the Himalaya mountains were supported at depth. Fisher (1881), who favored Airy’s hypothesis that the Himalaya were supported by a deep crustal “root,” concluded that the Earth’s crust was in a state of hydrostatic equilibrium and floated on its fluid substrate, much like an iceberg on seawater.

Today, we tend to think of isostasy as a restraining force rather than a driving force like ridge push or trench pull. Isostasy is a process that acts on the topography created, for example, at plate boundaries by continental rifting, break-up, and mountain building so as to reshape it and redistribute the stresses that have built up. The existence of regions of large topographic relief, unusually thick and thin crust, and large-amplitude gravity and geoid anomalies are all pointers that isostatic equilibrium does not prevail everywhere. The main challenge in isostatic studies has been to quantify the degree to which hydrostatic equilibrium of Earth’s crust is achieved and the time and spatial scales over which it operates.

A number of isostatic models have been proposed, three of which are illustrated in Fig. 1. Airy and Pratt are local models in which changes in the Earth’s topography are supported by either change in the thickness of a uniform density crust or by lateral change in density of the crust and/or mantle. Both models imply that the crust and mantle respond to loads (e.g., volcanoes) or unloads (e.g., erosion) locally such that neighboring regions are not involved in their support or removal. While the Airy and Pratt models are a potential source of stress in the crust (Bott and Dean 1972; Bott and Kusznir 1979) and may drive extension and compression they imply an intrinsically weak crust that responds to loads and unloads locally and in some cases by faulting. Vening Meinesz, on the other hand, is a regional model in which loads and unloads are supported by flexure of a thin elastic plate and stresses accumulate by bending.

It is important to remind ourselves that the models in Fig. 1 are highly idealized and only represent the state that the Earth's outermost layers would tend toward in the absence of disturbing forces. These disturbing forces include many of the great cycles of geology such as the waxing and waning of ice-sheets, the growth and decay of volcanoes, and sedimentation and erosion. Each process is potentially a disturbing force that could act to delay or even prevent isostatic equilibrium from being achieved.

There is now a considerable body of work that indicates Earth is a dynamic planet that is continuously being deformed. Isostasy, on the other hand, is a static concept that refers to a crust and mantle that has already moved and is now in equilibrium. It therefore appears at odds with current geodynamic views. But isostatic studies of the deformation that follows, for example, megathrust earthquakes, late-glacial rebound, volcano emplacement, and sediment accumulation provide “snapshots” of the way that the crust and

Isostasy, Fig. 1 The main types of isostatic models. Each model implies a state of hydrostatic equilibrium such that the Earth's outermost layers are in a state of flotation on their more fluid substrate. Names (e.g., Airy-Heiskanen) refer to the workers who first conceived and quantified the models. Vertical (lithostatic) stresses are constant on the depth of compensation in the Airy-Heiskanen (Airy 1855; Heiskanen 1931) and Pratt-Hayford (Pratt 1855; Hayford 1909) models and vary laterally in the Vening-Meinesz model (Vening Meinesz 1931). (a) Airy model: isostatic equilibrium is achieved by variations in the thickness of a

uniform low-density crust that overlies a high-density mantle. (b) Pratt model: isostatic equilibrium is achieved by lateral changes in the density. (c) Vening-Meinesz model: topography is considered as a surface load, and isostatic equilibrium is achieved by flexural downwarping and upwarping of the crust and mantle over a broad area. The load is supported by the strength of the lithosphere (which is determined by its effective elastic thickness, T_e) and the buoyancy of the underlying asthenosphere

mantle respond to loads and unloads over certain temporal and spatial scales (Watts 2007). Together, these “snapshots” provide information on whole lithosphere behavior and the clues as to how the crust and mantle would actually deform in response to continually applied loads and unloads.

A goal of isostatic studies has been to determine the vertical motion history of the Earth’s crust and mantle on short, through intermediate to long time-scales. Therefore, isostasy is central to studies of global change, especially those that are aimed at determining the relative role of tectonics and sea-level change in controlling the position of the shoreline today and in the geological past. Most significantly, isostatic studies provide information on how the lithosphere responds to the load and unload shifts that occur during climate-driven glacial and inter-glacial cycles. We are presently in an inter-glacial, for example, yet the isostatic effects of the Last Glacial Maxima (LGM) are still clearly visible today in tide gauge and satellite Global Positioning System (GPS) data. Isostasy is a key to understanding the lithosphere on which we live and how it interacts with the asthenosphere below and the cryosphere, hydrosphere, and atmosphere above.

Concepts and Applications

The isostatic models illustrated in Fig. 1 imply different gravity anomalies and crust and mantle structures. Airy and Pratt, for example, predict that free-air gravity anomalies will generally be small over volcanoes because they are underlain by either a thick, uniform-density, crustal “root” or a constant thickness low-density crust, the negative gravitational effect of which will compete with the positive effect of the volcano. Vening Meinesz, on the other hand, predicts a shallower depth to Moho beneath a volcano than Airy or Pratt and, hence, the free-air gravity anomaly will be generally large over a volcano because its gravity effect will now dominate over that of the compensation.

Figure 2 shows the topography, free-air, and isostatic gravity anomalies in the region of northern India where the early geodesists carried out their classical work. The isostatic anomaly has been calculated by subtracting (and thereby removing) the positive gravity effect of the topography and the negative gravity effect of the Airy compensation from the observed free-air gravity anomaly. The Root Mean Square (RMS) of the free-air gravity anomaly variation about its mean is 87.8 mGal while the RMS of the Airy isostatic gravity anomaly is 45.9 mGal. These RMS values show that the free-air gravity anomaly is substantially reduced after a correction for isostasy and so we may conclude that equilibrium prevails to a significant degree in the northern India region.

Despite this success, Fig. 2a shows that significant departures remain in the Airy isostatic anomaly map. The most

striking are the positive-negative anomaly “couples” that correlate with the edge of the Tibetan Plateau, particularly, its boundary with the Ganges and Tarim foreland basins. The negative anomalies are usually on the basin side while the positive anomalies are on the plateau side, which implies that the Moho is deeper than expected for Airy on the basin side and shallower on the plateau side. Such a Moho geometry can be explained if we assume that the load of the Himalaya and Kunlun Mountains is supported by the strength of the underlying crust and mantle which flexes over a broad region that extends beyond the mountains themselves. The Vening Meinesz model takes into account these ideas of loads and bending and Fig. 2c shows that when an elastic plate flexure model is used to compute the compensation rather than an Airy model then the RMS of the isostatic anomalies are reduced even further. A useful parameter in the Vening Meinesz model is the effective elastic thickness, T_e , since it is a proxy for the long-term strength of the lithosphere. Figure 2c shows that there is a well-developed minimum in the RMS of the isostatic anomaly for $T_e \sim 30$ km, suggesting this as the best fit T_e estimate for the region (see also Crosby 2007 who found a similar best fit T_e for the northern India region). This is, of course, only an average and so there will be areas that are stronger and areas that are weaker than this. Indeed, Braitenberg et al. (2003) and Jordan and Watts (2005) have already shown, using inverse methods, that T_e is <30 km over the central and northern Tibetan Plateau and >30 km over the Ganges and Tarim foreland basins.

Another way to test isostasy on a regional scale is to compare compilations of the seismically constrained crustal structure directly to the predictions of isostatic models. Figure 3 shows, for example, a 18,000 km long transect of the Indian, Atlantic, and Pacific Oceans along which observed and calculated depths to Moho are compared. The observed Moho is based on CRUST 2.0 (Bassin et al. 2000), a $2^\circ \times 2^\circ$ grid of P-wave velocity and crustal layer thickness data derived from active source seismic data. The calculated Moho is based on an Airy model with the same density and crustal thickness as used in Fig. 2. The figure shows that the calculated Airy Moho tracks the observed seismic Moho well, especially so at rifted margins and beneath some continents.

The main departures are in the central Atlantic Ocean where the observed Moho depth is shallower than predicted by Airy and beneath the Eastern US Appalachians the Gulf of Mexico and the Persian Gulf where the observed Moho depth is deeper. The shallower depths in the can be explained by our assumption of a relatively high subcrustal oceanic mantle density (3330 kg m^{-3}) which if reduced (e.g., to 3180 kg m^{-3}) beneath a mid-oceanic ridge would result in a shallower Moho depth and better agreement with the seismic Moho depths. The idea of a relatively low-density subcrustal mantle beneath the ridge suggests a Pratt rather than an Airy

Isostasy, Fig. 2 Topography, free-air, and isostatic gravity anomalies in the region of the Tibetan plateau. (a) Upper panel: Topography based on GEBCO (2003). The map shows the plateau and the flanking Tarim and Ganges foreland basins, the major faults (ATF = Altyn Tagh Fault, MBT = Main Boundary Thrust), and the north-south profile (thick red line) plotted in (b). Middle panel: Free-air gravity anomaly based on the EGM2008 2.5×2.5 min grid (Pavlis et al. 2008). Lower Panel: Airy isostatic anomaly calculated by subtracting the gravity effect of the topography and its compensating "root" from the observed free-air gravity anomaly. Calculations assume a density of water, crust, and mantle of 1030, 2800, and 3330 kg m^{-3} , respectively, and a zero

elevation crustal thickness of 31.2 km. (b) Predicted crustal structure based on the Airy and flexure models and free-air and isostatic gravity anomaly profiles of the Tibetan plateau at longitude 85°E . (c) Root Mean Square (RMS) of the isostatic anomaly as a function of elastic thickness, T_e , which is a proxy for the long-term strength of the lithosphere. The Moho depth for $T_e = 0$ km corresponds to the predictions of an Airy model which implies a plate with no strength. The minimum RMS and hence the isostatic model that best explains free-air gravity anomaly data in the vicinity of the Tibetan plateau is for a flexure model with $T_e = 30$ km

model of isostatic compensation. Indeed, the Pratt model has been assumed in thermal cooling models (Sclater and Francheteau 1970) for the variation of seafloor depth and heat flow with age and the model may well apply to other cases of thermal isostasy, for example, at mid-plate oceanic swells (Nakiboglu and Lambeck 1985) and fracture zones (Sibuet and Veyrat-Peinet 1980).

The deeper depths than predicted by Airy in Fig. 3 correlate with thick sediment accumulations in the Mississippi River Delta and the Zagros foreland basin. Here, sediment loads due to rifting and thermal contraction and thrusting and folding providing the accommodation space have flexed the Moho downwards over a broad area such that Moho is deeper than would be expected for an Airy model. The deeper depths

Isostasy, Fig. 3 Comparison of the crustal structure based on seismic refraction data to the predicted crustal structure assuming an Airy model along a 18,000 km long great circle profile that extends from the Pacific Ocean in the west across the Atlantic Ocean to the Indian ocean in the

east. The seismic refraction data is based on CRUST2.0 <http://igppweb.ucsd.edu/~gabi/rem.html> and the Airy model is based on the same parameters as assumed in Fig. 2

Isostasy, Fig. 4 Comparison of the observed crustal structure derived from seismic refraction data (Contreras-Reyes et al. 2010) to the predictions of an Airy and flexure model of isostasy along a NNE-SSW trending profile of the Louisville Ridge seamount chain at latitude 27.5° S, southwest Pacific Ocean. Black filled triangles indicate the location of the ocean bottom seismometers that were used to constrain the seismic structure of the crust. Thick solid red lines show the depth to the seismically constrained Moho. Thin solid black line separating the purple and pink filled regions show the 6.0 km/s P wave iso-velocity contour. Purple fill = volcanoclastic material. Pink fill = volcano edifice. Blue fill = deformed oceanic crust. (a) Airy model based on the same parameters as assumed in Fig. 2. (b) Flexure model with $T_e = 10$ km

beneath the Eastern US Appalachians are puzzling and may reflect a downward flexure related to thinner lithosphere, as defined by teleseismic studies (Rychert et al. 2005).

The role of flexure in contributing to crustal structure is well illustrated in Fig. 4 which shows the results of a recent seismic reflection and refraction survey of the Louisville

Ridge seamount chain near its intersection with the Tonga-Kermadec trench (Contreras-Reyes et al. 2010). The survey utilized a large-volume air gun source array and 39 ocean bottom seismometer receivers spaced ~15 km apart. The geometry was such that full ray coverage of the seamount and the underlying oceanic crust and uppermost ~10 km of

the mantle was achieved. Figure 4a shows that the seismic Moho (which is resolved here to ± 100 m) cannot be explained by an Airy model which predicts too deep a Moho beneath the seamount chain and too shallow a Moho in flanking regions. The best fit between observed and calculated Moho depths (Fig. 4b) is for a flexure model of isostasy with $T_e = 10$ km. Such a model explains well the observed depth to Moho beneath *both* the seamount edifice and flanking moat regions.

Current Investigations

One of the most important results to have emerged from isostatic studies over the past 40 years has been to show that a link exists between the T_e derived from flexural modelling and the long-term strength of the lithosphere. Data from experimental rock mechanics, for example, suggest that the strength of oceanic lithosphere is limited by brittle deformation in its uppermost part and by ductile flow in its lowermost part (Goetze and Evans 1979). This strength “profile” implies that loads applied to the surface (or base) of the lithosphere will be supported partly by the brittle and ductile strength of the lithosphere and partly by a central “core” which deforms elastically. It has been shown that oceanic T_e reflects the thickness of this “core” which will be small in regions of young crust, large loads, and high curvature of bending and high in regions of old crust, small loads, and low curvature (Watts and Burov 2003). Oceanic T_e is in the range 0–40 km and since the oceanic crust is only ~ 8 km thick, we may conclude that not only the crust but also the mantle is involved in supporting long-term geological loads.

Figure 5 shows that T_e at seamounts and ocean islands and deep-sea trench and outer rise systems increases with the age of the lithosphere at the time of loading, being small at volcano and trench loads that form on young seafloor (e.g., on-ridge) and large at loads on old seafloor (e.g., off-ridge). Thus, as oceanic lithosphere cools, subsides, and increases in age following its creation at a spreading center, it becomes more rigid in the way that it responds to loads. Interestingly, most seamount and oceanic island values fall within the 300–600 °C isotherm envelope based on the cooling plate model of Parsons and Sclater (1977), while most trench and outer rise values require a higher controlling isotherm in the region 450–800 °C. This difference in the range of controlling isotherm can be explained by difference in the load age, which is small (essentially present day) at deep-sea trench-outer rises and large (~ 1.5 to 100 Myr) at seamounts and oceanic islands. Indeed, a load age dependency explains much of the scatter in plots of T_e vs. age of the lithosphere at the time of loading. Other possible contributors are uncertainties in load, infill and mantle densities, thermal

perturbations due to hot and cold spots, and yielding in regions of large loads and high curvature.

Most of the T_e estimates plotted in Fig. 5 are based on a forward modelling approach in which the gravity anomaly, surfaces of flexure, or vertical motion history are calculated and compared to observations. The best fit T_e is then determined by a “trial and error” comparison of the observed and calculated. While forward modelling is a satisfactory way to estimate T_e , the number of sites where information on both load and plate age are available is limited.

Technological improvements in satellite radar altimetry and shipboard multibeam (swath) bathymetry data acquisition systems have led to the development of new analysis techniques and an increase in T_e estimates. Watts et al. (2006), for example, used satellite-derived gravity data together with a reciprocal admittance technique to predict bathymetry for different values of T_e . By comparing observed and calculated bathymetry, these workers obtained 9758 individual estimates of T_e , 291 of which were at sites where both load and plate age were known. They found a greater than expected scatter in global plots of T_e vs. age of the lithosphere at the time of loading with no clear indication of a controlling isotherm. Kalnins and Watts (2009) used satellite-derived gravity and shipboard bathymetry data and a sliding window admittance technique and found the controlling isotherm varied regionally. This may help explain some of the scatter in global plots of T_e against load and plate age. Bry and White (2007) used satellite-derived gravity and shipboard bathymetry data and an inversion technique to determine T_e along a number of fixed length profiles of deep-sea trench outer rise systems and found no evidence of a controlling isotherm. Hunter and Watts (2016), however, used a similar circum-Pacific data set and inverse modelling approach and found a strong dependence of T_e and plate age. They attributed the difference with Bry and White (2007) to a combination of factors which include: the manner of the long wavelength gravity field removal; the method used to calculate gravity anomalies; the constraint placed on bending moment; and the location of the trench axis.

One problem with spectral methods is the influence of window size on the recovered T_e (Crosby 2007). Windows need to be large enough to resolve the largest T_e and small enough to avoid “contamination” from more than one type of tectonic setting (e.g., on-ridge, off-ridge).

The physical meaning of T_e and its relationship to load and plate age is less clear in the continents than it is in the oceans. Unlike oceanic lithosphere, continental lithosphere has a multilayered rheology (Burov and Diament 1995; Meissner and Strehlau 1982) and there may be more than one brittle and ductile layer that supports an individual load or unload. In this situation, T_e is not a particular depth in the lithosphere but a measure of its integrated strength. Continental T_e will depend on both the curvature of flexure (which depends in turn on the

Isostasy, Fig. 5 Plot of T_e vs. age of the oceanic lithosphere at the time of loading. (a) Seamounts and oceanic islands and (b) Deep-sea trench and outer rise systems. The data is based on Table 6.1 in Watts (2001) with additional values from Freedman and Parsons (1986), McQueen and Lambeck (1989), and 15 other studies that have been carried out since 2000. Solid and dashed lines show the calculated depth of the 300 °C and 600 °C isotherms based on the cooling plate models of Parsons and Sclater (1977) and McKenzie et al. (2005), respectively

size of the load or unload) and how well individual competent layers are coupled, being low for high curvature and poorly coupled systems and high for low curvature and well-coupled systems (Watts and Burov 2003).

As in the oceans, continental T_e has been estimated using both forward and spectral modelling techniques. Most forward modelling estimates are based on fitting either the gravity anomaly or the surfaces of flexure (as inferred, for example, from basement depth data) at rift-type, strike-slip,

intra-cratonic, and foreland basins to model predictions. Sometimes, both gravity anomaly and depth to basement data are available and this yields most reliable estimates (Haddad and Watts 1999). Continental T_e estimates range from 5–100 km and no simple relationship has yet been found between T_e and load and plate age (Watts 2001). The data is suggestive, however, of some age dependence. Archaean and Proterozoic cratons, for example, are generally associated with high T_e values (>70 km) while Phanerozoic

and younger mountain belts generally have lower values (25–60 km) (Pérez-Gussinyé and Watts 2005). Young rifted margins (e.g., South China Sea) appear to have lower T_e values than old margins (e.g., Amazon) (Watts et al. 2009) and this has been interpreted as the result of heating during continental break-up, which weakens the lithosphere, and cooling following rifting that strengthens it (Burov and Poliakov 2001). Plume-influenced rifts (e.g., Afar, North Atlantic) are associated with the lowest T_e values (Ebinger et al. 1989; Watts and Fairhead 1997) but it is not clear how much strength the weakened rifted lithosphere in such tectonic settings is capable of regaining following a rifting event.

According to the Wilson Cycle, ocean basins open and close and compressional structures in mountain belts develop on or close to the site of extensional rifted margins. Isostatic studies of the foreland basins suggest that they may inherit the T_e structure of the underlying rifted margin (Lin and Watts 2002; Ali and Watts 2009). The foreland basin may be either narrow or wide, depending on whether it formed on a young or old margin. The very high (>70 km) T_e values that are associated with some foreland basins (e.g., central Andes) may be explained by the fact that the fold and thrust belts, the main driving load for foreland basin subsidence, will sometimes over-ride the rifted margin altogether and “telescope” onto the more rigid cratonic interior, thereby inheriting its value.

As in the oceans, spectral approaches have provided new insights into continental T_e , especially its spatial and temporal variation. The first studies (e.g., Dorman and Lewis 1970; Banks et al. 1977; McNutt and Parker 1978) were based on a Bouguer admittance, Fourier transform periodogram method, which generally yielded low values. Forsyth (1985), however, pointed out that the low values might be a result of subsurface (i.e., buried) loads that were uncorrelated with surface topographic loads. Subsurface loads are difficult to define and so he suggested using the Bouguer coherence, rather than the Bouguer admittance, because it was less sensitive to the ratio of surface to subsurface loading. Forsyth’s method has been widely applied (e.g., Zuber et al. 1989) and as Bechtel et al. (1990) showed for North America, it yields low as well as high values, especially in cratonic regions. Subsequent studies have incorporated new techniques, including maximum entropy estimators (Lowry and Smith 1995) and multitapers (McKenzie and Fairhead 1997). McKenzie and Fairhead (1997) recommend using the free-air admittance rather than the Bouguer coherence because the surface topography, unlike buried loads, is a known load, the gravity effect of which should not really be removed from the free-air gravity anomaly. Forsyth’s Bouguer coherence technique they argued maybe biased by the effects of erosion and his method will

yield over-estimates of T_e rather than true values. Pérez-Gussinyé and Watts (2005) used both Bouguer coherence and free-air admittance methods and found the highest values in Europe (>70 km) over the Archaean and Early Proterozoic (<1.5 Ga) East European craton (which is part of Baltica) and the lowest values (10–45 km) over the flanking Caledonian, Variscan, and Alpine orogenic belts (Fig. 6). Similar results were found for North and South America (Kirby and Swain 2009; Pérez-Gussinyé et al. 2007), Australia (Simons et al. 2000), and Africa (Pérez-Gussinyé et al. 2009) and a consensus seems to be emerging that the continental lithosphere is capable of showing both great weakness and great strength. Interestingly though, cratons are not always associated with a uniformly high T_e , and there exist regions within them that have low values.

In another development, wavelets have been used instead of spectral methods. Wavelets have an advantage over spectral methods in that they are local in space and scale so that the relationship between gravity anomaly and topography can, in principal, be examined over a range of wavelengths without the need for annular averaging over discrete windows. They generally yield similar results as spectral methods, although the recovered values of T_e tend to be smoother (Audet and Mareschal 2007; Sacek and Ussami 2009; Stark et al. 2003; Tassara et al. 2006).

Irrespective of the methods used, caution needs to be applied when interpreting continental T_e data. This is because it is not clear whether the T_e deduced from spectral studies refers to the same loading and unloading schemes as are assumed in forward modelling. In forward modelling, it is possible to discretize the loads (e.g., fold and thrusts) and flexures being considered, and the T_e deduced usually refers to a particular thermo-tectonic event in the geological past (e.g., a rift or orogenic event). Spectral methods, by way of contrast, “see” *all* the loads that are acting on the lithosphere, and these include not only loads in the past but sedimentary loads and erosional unloads, some of which continue to shape Earth’s surface topography up to the present day.

What is clear from all these studies is that Earth’s lithosphere has a rich T_e structure. In the oceans, T_e varies by up to ± 15 km over horizontal distances of 500–1000 km (Watts et al. 2006). Spatial variations are even larger in the continents. The compilations of Pérez-Gussinyé and co-workers, for example, suggest ± 25 km over similar distances. In many places (e.g., western Canada and USA), weak regions with T_e as low as 10 km abut strong regions with $T_e > 70$ km (Fluck et al. 2003). The consequences of such strength variations are profound, especially as they impact the computation of the isostatic gravity anomaly (Kirby 2019), the patterns of glacial isostatic rebound (Whitehouse et al. 2006), the solid earth tide

Isostasy, Fig. 6 The T_e structure of Europe as derived from the coherence between the observed Bouguer gravity anomaly and topography as a function of wavelength. Modified from (Pérez-Gussinyé and Watts 2005). (a) T_e and its relationship to the terrane structure. Thin white lines show major sutures. I = Iapetus, R = Rheic, A = Alpine. T = Thor. S = Sorgenfrei-Tornquist. The tectonic provinces are Ko, Kola; Ka, Karelia; and Svf, Svecofennian. Thin dashed lines show the Caledonian (Ca), Variscan (Va), and Alpine (Al) deformation fronts. Peri-G. = Peri-Gondwanaland. Av = Avalonia. EEC = East European Craton. Black filled circles show the location of the coherence and RMS plots in (b). (b) Examples of the observed and predicted Bouguer coherence and RMS between the observed (solid line) and calculated (dashed line) coherence for a 400×400 km and 1000×1000 km analysis windows centered on Belgium and northern Italy. Note that northern Italy appears as a region of low T_e in both windows, but the high T_e region of Belgium only has a clear RMS minima in the larger window

(Mantovani et al. 2005), and the terrane structure of continental lithosphere (Pérez-Gussinyé et al. 2007).

Current Controversies and Gaps in Knowledge

Isostatic studies have never been far from controversy as is evidenced by the vigorous debates on local vs. regional models that took place at the turn of the twentieth century. Central to these debates was the applicability of isostatic models to particular geological features and certain “schools of thought” emerged among geologists, geophysicists, and geodesists. There were even debates either side of the Atlantic when an Airy model was preferred by Europeans and a Pratt model by North Americans. Today, there is now general agreement on the relative role of local and regional models of isostasy. Debate is focused instead on the flexure model, particularly T_e , what it means and what it tells us about the long-term strength of the lithosphere, the time-scales of isostatic adjustment, and the geological processes that shape the top and base of the lithosphere.

The Long-Term Strength of the Lithosphere

In the oceans, there is widespread agreement on oceanic T_e and what it indicates about the long-term strength of the lithosphere. While there is scatter in plots of oceanic T_e vs. plate age, most of it can be attributed to viscoelastic stress relaxation (Watts and Zhong 2000), curvature and yielding (McNutt and Menard 1982), and spatial variations in the controlling isotherms that determine T_e (Kalnins and Watts 2009).

There has not, however, been the same agreement concerning continental T_e estimates and their relationship to age. The controversy came to a head in the so-called *crème brûlée* vs. *jelly sandwich* debate (Burov and Watts 2006). Proponents of the *crème brûlée* model follow McKenzie and Fairhead (1997) and Jackson (2002) who believe that because T_e is small and similar in thickness to the seismogenic layer, the strength of the lithosphere resides mainly in the uppermost part of the crust. In their view, the lower crust and uppermost mantle are weak which explains why deep earthquakes are rare. Proponents of the *jelly sandwich* model, however, follow Meissner (1986) who argue that the strength resides mainly in the upper crust and the uppermost mantle. In his view, only the lower crust is weak. This model is compatible with the results of seismic reflection profiling which show a layered lower continental crust and with the results of flexure studies which show a wide range of T_e values. Low T_e is indicative of thin competent layers while high T_e values reflect thick competent layers. Very high T_e values (>70 km) are also permissible, depending on composition, and occur when the upper and lower crust and/or the lower crust and mantle are coupled. Deep earthquakes are rare, not because the mantle is

too weak, but because it is too strong and the regional tectonic stresses required to initiate faulting and earthquakes are not large enough.

The debate has led to a reexamination of the methodologies used to estimate continental T_e , the physical meaning of T_e and the geological implications of a weak or strong mantle. Pérez-Gussinyé et al. (2004), for example, showed that it is necessary when comparing observed and calculated free-air admittances to first window them using the same multitaper estimator while Crosby (2007) showed that in order to recover T_e in cratonic shield regions, large window sizes (up to 1500 km) are needed. Otherwise, T_e maybe underestimated. Watts and Burov (2003) pointed out that while T_e may well be low and similar to the seismogenic layer thickness in some tectonic settings (e.g., Basin and Range, western USA), the two parameters are not the same. T_e reflects the integrated strength of the lithosphere while the seismogenic layer is the thickness of the uppermost part of the crust that responds to stresses by faulting and earthquakes. Finally, Handy and Brun (2004) argued that a strong uppermost mantle is required in order to explain the integrity of sinking slabs in subduction zones and the deep structure of rifted margins and orogens.

The continental T_e debate has proved a useful discussion point in isostatic studies. It highlights the importance of T_e while at the same time illustrates gaps in our knowledge about the Earth's lithosphere, especially regarding its long-term rheology. Other gaps are:

Time-Scales of Isostatic Adjustment

Isostasy varies temporally, as well as spatially. Exactly how slow or fast isostasy operates is of fundamental importance to our understanding of the Earth's vertical motion history as well as to topics such as sea-level change. For example, Bloom (1967) pointed out that the height of a wave-cut notch above present day sea-level depends not only on the amplitude of sea-level change but how quickly isostatic equilibrium is achieved. If isostasy is fast, then a sea-level rise will have time to load the crust and upper mantle and so the height of the notch will be low due to regional subsidence. If, on the other hand, isostasy is slow then there will be time and a notch will be cut at a higher elevation.

Several attempts have been made to estimate the time scales of isostatic adjustment associated with load shifts on the top or base of the Earth's crust. Watts (1978), for example, compared the T_e derived from oceanic flexure studies to the thermal and seismic thickness of the lithosphere and concluded that on loading there must be a rapid reduction in the thickness of the mechanical layer that supports a load as the lithosphere relaxes from its short-term seismic to its long-term elastic thickness. Beaumont (1979) used an elastic-plastic model based on the creep laws of olivine to argue that while oceanic lithosphere was essentially elastic on long-time scales, continental lithosphere would continue to relax on

time-scales of up to several tens of Myr. Willett et al. (1985) used a viscoelastic plate that overlies an inviscid substrate to model continental T_e data and showed that on loading there would be a weakening of the lithosphere that reduced the thickness of the mechanical layer by as much as a factor of 3–8, depending on the initial thermal structure of the lithosphere that was assumed. And finally, Watts and Zhong (2000) and Watts et al. (2013) have used the actual temperature structure of the oceanic lithosphere constrained from seafloor depth and heat flow data to calculate a viscosity profile and then examined how the equivalent T_e would vary following volcano loading. They showed that because viscosity increases from low values in the lower lithosphere to high values in the upper lithosphere, the lithosphere relaxes from the bottom-up such that stresses migrate upwards and the reduction in the thickness of the mechanical layer that supports a surface or subsurface load is initially fast and then slows with increase in the load age.

Figure 7 compares the T_e for a number of seamounts and ocean islands in the world's ocean basins to predicted curves based on a multilayered viscoelastic model. The model

assumes an asthenosphere viscosity of 10^{21} Pa s and a lithosphere viscosity that increases from 10^{21} Pa s to 10^{35} Pa s, depending on thermal age. The figure shows a rapid decrease in the thickness of the lithosphere that supports a load and hence a decrease in its strength. This weakening results in an increase in subsidence and a narrowing of the zone of subsidence with increase in load age. Eventually, the strength reduction slows and the thickness that supports a load approaches a steady state value.

The continents display a wider range of load and unload ages than the oceans and elastic thickness estimates have now been published for short-term (a few s to a few hundred s) earthquake loading (2–100 s) through intermediate (~10 ka) glacial isostatic rebound to long-term (>1 Ma) flexure. There are regions (e.g., western and eastern USA) where elastic layer thickness has been estimated for two or more timescales. These data suggest that the relaxation observed in oceanic lithosphere may also characterize continental lithosphere, albeit over a much wider range of relaxation time-scales. For example, the Hebgen Lake (Nishimura and Thatcher 2003), Lake Bonneville (Nakiboglu and Lambeck 1983),

Isostasy, Fig. 7 Plot of elastic layer thickness vs. age of load for oceanic and continental lithosphere. Modified from Watts (2007). The thick solid blue line and thin dashed blue lines show the predicted change in elastic layer thickness for young, intermediate, and old oceanic lithosphere according to Watts and Zhong (2000). Filled blue circles show the data from individual seamount and ocean island loads which range in age from ~1–100 Myr. The data indicate that by ~10 kyr oceanic loads have undergone most of their relaxation. The thick dashed brown lines show the predicted change in elastic thickness for continental lithosphere. Filled grey rectangles are based on earthquake loading (post-seismic and co-seismic), filled blue rectangles are based on glacial isostatic

adjustment and filled beige and yellow rectangles are based on continental flexure studies (see Watts 2007 for references). Open symbols show elastic layer thickness estimates from the same tectonic region (circles = western USA, squares = eastern USA) based on the data in Nakiboglu and Lambeck (1983), Di Donato et al. (2000), Lowry et al. (2000), Nishimura and Thatcher (2003), and Pazzaglia and Gardner (1994). The data suggest two modes of relaxation that correspond to “fast” and “slow” isostasy. Interestingly, the relaxation time separating these modes varies between oceans and continents with western USA relaxing much quicker (~10 yr) than the oceans and eastern USA much slower (~70 Myr)

and western Cordillera (Lowry et al. 2000) loads which reflect ages of 0–120 s, 10 ka, and ~60 Ma are associated with elastic layer thicknesses of 38, 30, and 5 km, respectively. T_e therefore decreases with increase in load age. The decrease is similar in form to the ocean loading cases modelled by Watts and Zhong (2000) and Watts et al. (2013), but the viscosity of the asthenosphere required is less and $\sim 3 \times 10^{18}$ Pa s. This viscosity results in a rapid initial and a slow final weakening of the lithosphere and a transition between the two weakening regimes at load ages of ~30 a. Interestingly, the transition age appears to vary regionally such that loads on tectonic western North America relax quicker than those emplaced on the more stable parts of eastern North America (Watts et al. 2013).

Isostasy and Landscape Evolution

The behavior of the lithosphere and how it interacts with the cryosphere, hydrosphere, and atmosphere above and the asthenosphere below is a fundamental question that needs to be addressed if we are to fully understand geological processes and construct realistic models. We know, for example, from flexure studies that the lithosphere behaves as a low-pass filter in the way that it responds to loads and unloads, suppressing the short-wavelength deformation and passing the long-wavelengths. The physical properties of the lithosphere therefore smooth out the effects of surface and subsurface processes such as those involved in landscape evolution

and mantle convection, making it difficult to see the full effect of these processes.

It is being increasingly recognized that isostasy plays a major role in the development of landscapes and seascapes, both in the constructive forces such as tectonics that build them and the destructive forces such as erosion and large-scale slope failures that destroy them. Examples include the flexures that follow mechanical unloading on normal faults (ten Brink and Stern 1992), fault scarp retreat (Gilchrist and Summerfield 1990), and glacial erosion (Pelletier 2004; Stern et al. 2005). Because flexure involves rock uplift and subsidence it is capable of modifying the landscape, especially river knickpoints, base levels and pre-existing drainage basins. This is particularly well seen in the rim uplifts that flank rifts (Tucker and Slingerland 1994) where flexure is a major factor in controlling the drainage divide that separates scarp and dip streams. Other examples have been described from the Cotswold Hills, southern England (Lane et al. 2007) where rim uplifts flank regions of fluvial incision and excavation.

Figure 8 illustrates the isostatic adjustment that would occur following fluvial incision and excavation of a 150 m deep, 60 km wide, region of relatively low-density sediments. The calculations assume that the lithosphere behaves as a viscoelastic plate, similar to that implied by the T_e data in Fig. 7 and used by Watts and Zhong (2000) to calculate the time-dependant flexure that follows seamount loading. The

Isostasy, Fig. 8 Simple model for flexure of the lithosphere due to river incision and excavation. The model assumes that the lithosphere responds to loads (and unloads) initially as a thick elastic plate ($T_e = 80$ km), then as a viscous material and finally as a thin, essentially elastic, plate ($T_e = 10$ km). The response shows an initial long-wavelength, low-amplitude uplift a transient short-wavelength high-amplitude uplift and subsidence and a final short-wavelength high-amplitude uplift and subsidence that together reflects the thinning of the lithosphere from its initial short-term thickness to its long-term elastic thickness. Thick solid red line shows the final topography after it has been modified by slope diffusion (assumed erosion time = 50 ka, diffusion constant = $50 \text{ m}^2 \text{ a}^{-1}$)

main model features are an initial thick-plate elastic response, a viscous time-dependent response, and a final thin-plate, essentially elastic, response. The figure shows that lithospheric weakening due, for example, to load-induced stress relaxation has the capacity to create topography that locally either enhances or subdues the more regional deformation associated with the initial short-term response. Karner (1984) showed that topography is also created during lithospheric strengthening when, for example, the oceanic lithosphere is thermally rejuvenated (and weakened) at midplate hotspot swells and subsequently cools. The topography in this case subdued the original swell.

Incision and excavation, together with refilling, are common features of the fluvial response to glacial and inter-glacial cycles. Isostasy will therefore have a major role to play in the deformations that result. For example, incision due to melt-water charged rivers is a feature of glacial periods when sea-level was low while valley filling and delta construction are features of inter-glacials when sea-level was high. Repeated episodes of incision and valley fill will therefore re-surface a landscape, creating in the process isostatic rim uplift and subsidence, as seems to have occurred in the region of the Mississippi River where it debauches in to the Gulf of Mexico (Blum et al. 2008). One consequence of this resurfacing is that apparent sea-level may vary along-strike the northern Gulf of Mexico rifted margin such that the Mississippi River valley in Texas is presently subsiding relative to the adjacent Alabama coast.

The Earth's lithosphere is deformed not only by surface geological loads and unloads but also by subsurface loads, some of which originate within the crust while others have their source in the subcrustal mantle. Like surface loads, subsurface loads are associated with mass excesses and deficiencies and create flexures of the Moho and other crustal layers that are manifest in topography and gravity anomaly data. For example, subsurface loads due to sinking down-going slabs, intra-crustal thrusting, obduction, and ophiolite emplacement cause flexures that contribute to both topography and gravity anomalies (e.g., Royden and Karner 1984; Lin and Watts 2002; Ali and Watts 2009).

Long-Wavelength Gravity and Topography Anomalies, Isostasy, and Mantle Dynamics

It has been known since the pioneering studies of Kaula (1967) that Earth's gravity field spectrum is rich and has significant power at short as well as long wavelengths. Isostatic loads and unloads, however, are compensated so that their associated gravity anomaly will be reduced and may approach zero at the longest wavelengths. This is clearly seen in the theoretical free-air admittance which shows that Airy, Pratt, and flexure models have a distinct "roll-over" that approaches zero at the longest wavelengths because of isostasy (Watts 2001). The existence in oceanic regions of

observed admittances in the range 5–20 mGal km⁻¹ at wavelengths of 1000–4000 km (Crosby 2007; Watts 2007; Wicczorek 2007) is therefore of much geodynamic interest. Watts (2007) has shown that the long-wavelength admittance remains approximately constant at ~18 mGal km⁻¹ in the central Pacific Ocean as the analysis window size is increased from 1000 to 4000 km. He argued that the long-wavelength admittance cannot be attributed to isostasy and so must reflect dynamic processes in the subcrustal mantle.

As McKenzie (2010) has shown, continents, like the oceans, are characterized by a high admittance at long wavelengths. The higher values he obtained (35–50 mGal km⁻¹) are expected since topography displaces air in the continents rather than water thereby increasing the contribution of the gravity effect of the topography. The observation of high, positive, admittances at long wavelengths in both oceans and continents is interesting, especially as it suggests a degree of correlation between gravity and topography at these wavelengths.

A correlation between long wavelength gravity and topography was noted by Kaula (1967) and as McKenzie (1977) points out, makes a strong argument for some form of mantle dynamics. Density-driven convection, for example, has the potential to contribute to the free-air gravity anomaly and the surface topography in both upwelling and downwelling regions. Long-wavelength topography that cannot be attributed to isostasy has been dubbed a "depth anomaly" by Menard (1973) and "dynamic topography" by (Hager et al. 1985) and convection maybe a significant contributor to the depth of mid-plate swells (Watts 1976), old (Huang and Zhong 2005) and young (Marks et al. 1990; Crosby and McKenzie 2009) ocean floor, the subsidence and uplift history of foreland-type (Liu and Nummedal 2004), rift-type (Muller et al. 2000), and some intra-cratonic sedimentary basins (Coakley and Gurnis 1995). An outstanding question is how best to separate the effects of isostasy from gravity anomaly and topography data and isolate the planform of motions in Earth's mantle.

Some progress on the problem has now been made by better defining the wavelength band of flexural isostasy. Figure 9 shows, for example, a plot of the power spectral density (in mGal²) of Earth's free-air gravity anomaly as a function of spherical harmonic degree and equivalent wavelength. The figure shows the power spectra increases at short wavelengths (<400 km), flattens at intermediate wavelengths (400–1100 km), and then rises again at long wavelengths (>1100 km). The rise at short wavelengths follows the predictions of a model in which topography is uncompensated. The flattening at intermediate wavelengths suggests some degree of compensation of topography, although not in the form as predicted by the Airy model of isostasy. The observed spectra are clearly higher than the calculated spectra in this wavelength band and suggest instead a flexure model of

Isostasy, Fig. 9 Comparison of the power spectrum of Earth's free-air gravity anomaly field (filled black circles) to calculated spectra based on the gravity effect of uncompensated topography (Red filled circles) and the gravity effect of the topography and its Airy compensation (Green filled circles) and flexural compensation (Light blue filled circles). From Watts and Moore (2017). The observed spectra have been calculated from the spherical harmonic coefficients that describe the EGM2008 gravity field model (Pavlis et al. 2008) and the uncompensated and isostatic spectra have been calculated using equations in Kaula (1967)

and Watts and Moore (2017) and the Earth2014 topography model of Hirt and Rexer (2015). Grey band = twice the minimum Root Mean Square (RMS) difference between the observed spectra and the calculated spectra based on a flexure model of isostasy, used to define a region of permissibility for the best fit elastic thickness, T_e . HDB = High Degree Band. LDB = Low Degree Band. Inset shows the RMS difference between observed spectra and calculated spectra of the gravity effect of the topography and its flexural compensation as a function of T_e . The best fit global T_e is 34.0 ± 4.0 km

isostasy with a T_e of 34.0 ± 4.0 km. This range of T_e is interesting, especially as it is a global mean and indicates that there are regions of Earth with lower and higher values. The rise at long wavelengths (>1100 km) cannot be explained by the gravity effect of the flexure model of isostasy, or any other isostatic model, and therefore defines for us the limits of isostasy and the role played by non-isostatic processes such as those associated with mantle convection in contributing to Earth's gravity field spectra. Improved gravity anomaly, topography and seismic field data, localized spectral analysis techniques, and better geodynamical models that include a lithosphere offer the most promise of better quantifying the contribution of isostasy to Earth's gravity and topography fields and crustal structure in the future.

Conclusions

Isostasy is a principle that is central to the Earth Sciences. It was first formulated in the 1880s to describe the tendency of

the crust to float, in hydrostatic equilibrium, on its denser substrate such that light areas stand at a greater elevation than dense areas. Today, we consider isostasy as a highly idealized state that the crust and upper mantle approaches, but rarely achieves. Nevertheless, the comparison of observed gravity anomalies to the predictions of local and regional isostatic models have led to a new understanding about the thermal and mechanical properties of the lithosphere. We now know, for example, that the lithosphere responds to long-term (i.e., $>10^5$ years) loading and unloading in a similar manner as would a strong elastic plate that overlies a weak fluid substrate. In the oceans, the thickness of the elastic layer that supports a volcano load increases with the age of the lithosphere at the time of loading. In the continents, the relation between elastic thickness and age is not as clear. However, there is evidence that older Archaen and Early Proterozoic cratons have high values of the elastic thickness (i.e., >70 km) while younger Middle/late Proterozoic and Phanerozoic orogenic belts and rifts have lower values. Data from experimental rock mechanics suggest that the elastic

thickness derived from isostatic studies is a proxy for the long-term strength of the lithosphere. The elastic thickness differs from the seismogenic layer thickness, which is the thickness of the uppermost part of the lithosphere that responds to stresses by faulting and earthquakes and the seismic “lid” thickness, which is the mechanical thickness that supports short-term loads and unloads. Isostatic studies suggest that the time-scales of isostatic adjustment varies regionally such that tectonically active areas respond to loads and unloads much quicker than cratonic areas. The behavior of the lithosphere on seismic to geologic time-scales is important to take into account when modelling geological processes, especially those linking dynamic topography and mantle convection.

Definition

Isostasy

(Greek: isos “equal,” stasis “standstill”) term used in geology to refer to the condition of gravitational equilibrium such that the rigid outer part of Earth's crust and uppermost mantle “float” at an elevation which depends on its density. This concept explains how different topographic heights can exist at Earth's surface.

Compositional isostasy

The part of isostasy traceable to density variations arising from compositional (rock type and mineralogy) differences.

Thermal isostasy

The part of isostasy traceable to density variations arising from temperature differences and thermal expansion within the rock column.

Isostatic equilibrium

The condition whereby a certain area of crust and upper mantle reaches the state of isostasy such that a hydrostatic equilibrium exists at depth below a level of compensation. The region is said to be in *isostatic equilibrium*.

Introduction

The condition in Earth whereby variations in crustal thickness and density determine the elevation of Earth's solid surface is known as isostasy and has been appreciated for a century and a half (Pratt 1855; Airy 1855; Watts 2001, for general review). Local isostasy requires a hydrostatic equilibrium condition at a depth below a compensation level, implying that the integral of density over a rock column is constant. When density differences arise from differences in rock composition (rock type, mineralogy), the isostatic condition is referred to as compositional isostasy. It is compositional isostasy, and in particular the density contrast across the crust–mantle boundary, that dominates isostasy discussions in textbooks. If, on the other hand, density differences arise from different thermal states of the lithosphere and thermal expansion of rock, the condition is properly called thermal isostasy. This entry is

devoted to thermal isostasy, computation of thermal isostasy effects, and examples of thermal isostasy in oceanic regions and on the continents.

Thermal Isostasy

Rock density is influenced by temperature through thermal expansion. If rock composition is identical in two vertical columns through the lithosphere, the warmer column has a lower density than the cooler lithosphere. Applying the isostatic condition of hydrostatic equilibrium at some depth of compensation leads to a prediction of elevation changes for the two regions.

Consider two regions of different lithospheric thermal states. Temperature differences between the two regions represented by a regional geotherm $T(z)$ and a reference geotherm $T_{\text{ref}}(z)$, respectively, multiplied by a thermal expansion coefficient α_V and integrated over depth predict an elevation change, $\Delta\epsilon_T$, given by

$$\Delta\epsilon_T = \alpha_V \int_0^{z_{\text{max}}} [T(z) - T_{\text{ref}}(z)] dz. \quad (1)$$

The maximum depth of integration, z_{max} , is the depth at which the colder geotherm converges to a mantle adiabat assumed to be identical for both lithospheric regions.

Most studies use a coefficient of thermal expansion of $3.0 \times 10^{-5} \text{ K}^{-1}$ within the crust, consistent with the values for major crustal forming rocks including granite and gabbro. Within the mantle, a value of thermal expansion of $3.2 \times 10^{-5} \text{ K}^{-1}$ is used.

Oceanic Thermal Isostasy

The clearest example of thermal isostasy occurs in oceanic regions as hot, near-molten lithosphere at a spreading ridge

cools over tens of millions of years leading to thermal contraction, increasing rock density, and subsidence of the seafloor by about 3,000 m. It is important to note that lateral compositional variations are small in oceanic regions. Oceanic crust about 7 km thick is formed at a spreading center and its thickness and composition are modified only in minor ways over its maximum 165 My existence. The thermal state of oceanic lithosphere, on the other hand, varies from a near molten state at the ridge to extremely cold lithosphere after up to 165 My of cooling. These contrasting thermal states have consequences for the rigidity of the lithosphere but in particular for its density and therefore elevation.

Almost since the discovery of plate tectonics and seafloor spreading, thermal isostasy has been invoked to explain the bathymetry of the oceans as a function of age. Figure 1a illustrates the time evolution of an oceanic geotherm for a cooling plate model. The initial condition is 1,450 °C (Stein and Stein 1993); other cooler values lead to similar subsidence curves if thermal expansion values are adjusted accordingly. The ocean lithosphere initially cools rapidly as shown by the large difference between the 0.5 My geotherm and the 5 and 25 My geotherms (Fig. 1a). At longer times, the cooling slows and the geotherms reach near steady state shown by the 150 My geotherm. The average temperature change in the lithosphere between zero age at the ridge and about 150 My seafloor is 725 K.

Bathymetry is proportional to the integrated cooling of the oceanic lithosphere (Eq. 1), additionally incorporating the changing load of water as the seafloor subsides. This subsidence (Fig. 1b) is explained very well by a simple one-dimensional (1-D) model of lithospheric cooling. A midocean ridge, or zero age lithosphere, has on average a depth of 2.7 km, a consequence of both its thermal state, crustal thickness, and composition. But as the lithosphere ages and cools, temperature changes but crustal thickness and composition do not. Cooling over the first 9 My causes a subsidence of 1 km to a depth of 3.7 km. At a lithospheric age of 36 My, the solid surface has subsided a further kilometer to a water depth of

Isostasy, Thermal,

(b) Subsidence of the seafloor as a function of seafloor age. Solid dots are data in 2 My age bins. Gray shading represents ± 1 standard deviation about the mean bathymetry.

4.7 km. As the lithosphere reaches its thermal equilibrium, the bathymetry also approaches its equilibrium value of 5.5 km.

Continental Thermal Isostasy

On continents, thermal isostasy has been used successfully to examine the evolution of regions that mimic oceanic spreading, such as continental rifts and elements of provinces with extensive volcanism or back-arc regions (McKenzie 1978; Jarvis and McKenzie 1980; Brott et al. 1981; Lachenbruch and Morgan 1990; Hyndman et al. 2005). However, direct thermal effects on continental elevation are difficult to discern because of the potential masking effect of compositional variations in lithospheric density and crustal thickness.

The elevation effect due to compositional variation can be estimated by a simple isostatic calculation using continental extremes. A mountainous region with a crustal thickness of 50 km and a density of $2,800 \text{ kg m}^{-3}$ (granodiorite) would have an elevation 5 km higher than a rift province with a crustal thickness of 25 km and a density of $2,900 \text{ kg m}^{-3}$ (gabbro). Both columns assume a similar mantle density of $3,340 \text{ kg m}^{-3}$. The potentially large compositional effect can easily mask the effect of thermal isostasy. Therefore, in order to isolate the effect of thermal isostasy in the continents, it is necessary first to remove compositional isostatic effects.

Normalizing Compositional Elevation

Compositional variations involving both crustal thickness and density are removed with a simple isostatic correction to

the observed elevation (Han and Chapman 1995). The adjustment normalizes any crustal column to an arbitrary crustal standard. In refining this method, Hasterok and Chapman (2007a) used a standard crustal thickness h'_c of 39 km and a standard crustal density ρ'_c of $2,850 \text{ kg m}^{-3}$. These values represent the average crustal thickness and density of North American provinces. A lithospheric mantle density of $3,340 \text{ kg m}^{-3}$ is used based on the xenolith derived estimate by Griffin et al. (1999) for Proterozoic lithosphere.

Consider a crustal column with a crustal thickness, h_c , and crustal density, ρ_c , at an elevation of ϵ_{obs} (Fig. 2a). If the density and thickness of the observed crustal column are adjusted to match the standard density and thickness, the elevation would change by an amount $\Delta\epsilon_c$ (Han and Chapman 1995) given by

$$\Delta\epsilon_c = h'_c \left(1 - \frac{\rho'_c}{\rho_m} \right) - h_c \left(1 - \frac{\rho_c}{\rho_m} \right) \quad (2)$$

where ρ_m is the density of the mantle. If the province surface is below sea level (e.g., continental shelf), an additional term involving the water depth (where ϵ_{obs} is the bathymetry) and seawater density, ρ_w , is required and the elevation adjustment becomes

$$\Delta\epsilon_c = h'_c \left(1 - \frac{\rho'_c}{\rho_m} \right) - h_c \left(1 - \frac{\rho_c}{\rho_m} \right) - \frac{\epsilon_{\text{obs}} \rho_w}{\rho_m}. \quad (3)$$

By adding the elevation adjustment to the observed elevation, one arrives at the final adjusted elevation, ϵ_{adj} , given by

Isostasy, Thermal, Fig. 2 Compositional isostasy adjustments to continental elevation. (a) Cartoon illustrating parameters used in compositional correction for elevation. MSL is mean sea level and DOC is the depth of compensation. The observed crustal columns (*left* for regions above sea level and *right* for continental margins below sea level) are adjusted to an arbitrary standard crust (*center*) of thickness 39 km and

density $2,850 \text{ kg m}^{-3}$. (b) Nomogram contouring the compositional elevation adjustment for observed crustal thickness and average crustal density. Contour interval is 0.5 km. Dashed lines for crustal thickness of 39 km and density of $2,850 \text{ kg m}^{-3}$ represent the standard crustal column. Zero line is locus of values for which the elevation adjustment is zero.

$$\varepsilon_{\text{adj}} = \varepsilon_{\text{obs}} + \Delta\varepsilon_{\text{C}}. \quad (4)$$

Three important physical parameters must be estimated in order to make the compositional adjustment: ε_{obs} , h_{C} , and ρ_{C} . The observed elevation is obtained from GTOPO30 for elevations above sea level and from bathymetric maps for elevations below sea level. Crustal thickness is obtained from 1-D whole crustal V_{P} models. Crustal density is estimated by using empirical velocity–density (V_{P} – ρ) relationships. The lateral dimension of each province analyzed varies from ~ 70 km in some provinces in the Western USA to >500 km in shield provinces. See Hasterok and Chapman (2007a, b) for details.

The magnitudes of compositional elevation adjustments made using Eqs. 2 and 3 are shown in Fig. 2b. The zero contour is the locus of crustal thickness and density combinations for which no crustal adjustment is made and therefore passes through the standard crust of thickness 39 km and density $2,850 \text{ kg m}^{-3}$. Over the extreme range of crustal thicknesses (20–60 km) and densities ($2,700$ – $3,000 \text{ kg m}^{-3}$), compositional elevation adjustments can be as much as 4 km. Regions that are thinner and/or more dense than the standard crust receive positive elevation adjustments, whereas regions that are thicker and/or less dense than the standard crust receive negative elevation adjustments. Most adjustments in Fig. 2b fall in the range ± 1 km. From this nomogram we can also determine the uncertainty in elevation adjustment introduced by variations in crustal thickness and density. For example, to achieve an uncertainty of ± 250 m requires an uncertainty in crustal thickness less than 3 km and in density less than 43 kg m^{-3} .

Continental Thermal State

The thermal state of continental lithosphere is described by a set of geotherms. Whereas oceanic geotherms may be identified in terms of age, continental geotherms do not correlate well with rock age. Instead, the most important controlling parameter for continental geotherms is surface heat flow (Pollack and Chapman 1977b; Chapman and Pollack 1977; Blackwell 1971; Lachenbruch and Sass 1977; Rao et al. 1982).

There exist a number of geotherm models of the continental crust (Blackwell 1971; Lachenbruch and Sass 1977; Chapman 1986; Chapman and Furlong 1992). Many other models are based on locally derived estimates of thermal conductivity and/or heat production. Although locally and xenolith-derived models may be best in the region for which they are developed, they may be poor estimates when extended to other regions. Therefore, we feel it is best to use a consistent geothermal model based on the fewest parameters necessary to demonstrate the usefulness of this method. We chose the method of Chapman (1986) and Chapman and Furlong (1992) to compute our geotherms because they yield a set of geotherms that are well documented, commonly

used, and yield temperatures which fall between other warm and cool models.

The properties of the geotherm model include a lithospheric structure divided into an upper and lower crust and mantle lithosphere. Thermal conductivity within the crust is determined using a pressure-/temperature-dependent relationship of Chapman (1986). Thermal conductivities within the upper and lower crust are initially set as 3.0 and $2.65 \text{ W m}^{-1} \text{ K}^{-1}$, respectively, corresponding generally to felsic and mafic crystalline rocks at STP conditions. Mantle lithospheric thermal conductivities include a radiation term at temperatures above 500 K . Surface heat production is determined assuming a 40% radiogenic contribution to surface heat flow with a characteristic depth of 8 km (Pollack and Chapman 1977a). This characteristic depth is also used as the decay length of an exponentially decreasing function used to compute heat generation within the upper crust. Heat production of the lower crust is set as $0.4 \mu\text{W m}^{-3}$ consistent with many studies of exposed granulite terranes. Mantle heat production is assumed to be $0.02 \mu\text{W m}^{-3}$, a lower value justified by Chapman (1986) and Chapman and Furlong (1992). Temperatures within the asthenosphere are computed using an adiabat with a potential temperature of $1,300^\circ\text{C}$ and increase with depth of $0.3^\circ\text{C km}^{-1}$. Steady state, 1-D, conductive continental geotherms computed for surface heat flow values between 40 and 100 mW m^{-2} are shown in Fig. 3a. Details of the geotherm calculation and boundary conditions used are given by Chapman (1986) and further discussed in Hasterok and Chapman (2007a).

The thermal structure in some regions differs from the geotherm models used in this study as a result of nonsteady state processes and differences in thermophysical properties. However, we have chosen to keep our thermal models as simple as possible, interpreting the more difficult and uncertain parameters, that is, heat production and thermal conductivity, as residuals from a reference thermal isostatic model.

Revealing Thermal Isostasy on Continents

Because the thermal state of continents is not clearly related to the age of the lithosphere as it is in the oceans, one cannot confirm continental thermal isostasy by simply plotting elevation of continental regions against age of the province. Other approaches must be explored. One such approach examined elevation as a function of heat flow for several tectonic provinces around the globe (Han and Chapman 1995; Nagihara et al. 1996). Hasterok and Chapman (2007a, b) followed the same approach in much greater detail and made an assessment of the uncertainties related to removing compositional isostatic effects.

A thermal isostatic curve for the continents, derived from the geotherm family in Fig. 3a and Eq. 1, is shown in Fig. 3b. We use a reference geotherm corresponding to a surface heat flow of 47 mW m^{-2} and assign a lithosphere having this

Isostasy, Thermal, Fig. 3 Thermal isostasy on continents. (a) Generalized family of continental geotherms parametric in surface heat flow values from 40 to 100 mW m⁻². Geotherms are truncated by the 1,300 °C mantle adiabat. (b) Observed elevation versus heat flow for individual tectonic provinces of North America. Symbols denote dominant style of tectonic province: circle (shield), star (basin), square (collision), diamond (volcanic), triangle (extension). Error bars are one standard

deviation of the mean for heat flow. The geotherms in (a) together with Eq. 1 are used to calculate a theoretical thermal isostasy relationship shown as a bold line. (c) Elevation adjusted for compositional effects versus heat flow for the same tectonic provinces in (b). Elevation error bars are predicted from a Monte Carlo analysis of uncertainties in the seismic velocity to density conversion. Data trend confirms expected 3,000 m of thermal isostasy effect.

thermal state an elevation of 0 km. Although the zero elevation reference heat flow at 47 mW m⁻² is assumed here, the actual zero elevation could easily be set at another value. This initial assumption for the zero-elevation reference heat flow is refined further by Hasterok and Chapman (2007b). Within the range of surface heat flow for continental tectonic provinces (40–90 mW m⁻²), the predicted elevation range resulting from thermal isostasy is approximately 3 km. This prediction is similar to the oceanic bathymetry difference between hot ridges and cold abyssal plains.

Figure 3b also demonstrates how much continental thermal isostasy is obscured by compositional effects. There is little correlation between observed elevation of 36 North American tectonic provinces and the continental thermal isostatic curve. Much of this scatter is the result of variations in crustal density and thickness between the different tectonic provinces.

Compositional elevation adjustments for the 36 tectonic provinces of North America range from 763 ± 221 m in the Middle Rocky Mountains to $2,207 \pm 119$ m in the Gulf of California (Hasterok and Chapman 2007b). Nearly all of the provinces have compositional elevation adjustments between -1 and +1 km. The results suggest that the compositional contribution to the elevation of North America accounts for ~3 km of observed elevation variation. Patterns are evident in variations of elevation adjustment as a function of crustal thickness and density (Fig. 3c). The magnitude and range of elevation adjustments correlate with the type of tectonic regime that characterizes each North American province. Precambrian cratons have compositional adjustments between -0.5 and +0.5 km. Cenozoic rifts have elevation adjustments >0.5 km, and adjustments for volcanic provinces range from just under 0–1.0 km. Collisional orogens have a

very large range of elevation adjustments relative to the other tectonic environments, ranging from 0.75 to 1.0 km.

The elevation adjustment is added to the observed elevation to determine the compositionally adjusted elevation (Fig. 3c). Although the data shown in Fig. 3c exhibit much scatter, two trends are clear. First, the adjusted elevation difference between hot and cold provinces is ~3 km, a magnitude roughly equal to the elevation range observed in the oceans between hot spreading centers and cold abyssal plains. Second, whereas observed elevations do not define a clear trend with heat flow, the adjusted province elevations are less scattered and define a pattern that more closely resembles our predicted thermal isostatic curve (black line). The considerable scatter in Fig. 3c may be caused by imperfect compositional adjustment (seismic velocity characterization, velocity to density transform), by regions not being in isostatic equilibrium, or by surface heat flow not being perfectly representative of the thermal state of the lithosphere as described by the geotherm model used.

The North American Cordillera

The elevation of the North American Cordillera provides an excellent case study for thermal isostasy. Conventional wisdom suggests that many continental mountain belts, the result of continent–continent collision, are elevated because the collision process has thickened the continental crust. Airy isostasy considerations predict terrain elevations of 1,000–2,000 m as a result of thickened crust. But Hyndman (2010) point out that modern seismic data reveal that many of these collision provinces, in particular the North American Cordillera, do not have crustal roots. The Canadian Cordillera, for example, has a crustal thickness of only 35 km in comparison to the Canadian Shield crustal thickness of 40 km. But the elevation of the

thinner crust Cordillera is more than 1,000 m higher than the Canadian Shield, exactly opposite to the Airy compositional isostasy prediction.

The solution to this apparent conundrum is found in thermal isostasy (Hyndman 2010). Hyndman et al. (2005) and Currie and Hyndman (2006) have shown that high upper mantle temperatures characterize most subduction back-arc regions (see also Lewis et al. 1992, 2003). And that many mountain belts also occur in current or recent back-arc locations. The temperature-depth field for the Cordillera, therefore, is much hotter than for a cratonic region (Fig. 4a). The Cordillera geotherm approaches a mantle adiabat at a depth of about 60 km, defining the lithospheric thickness for the Cordillera, while the Craton geotherm does not approach the mantle adiabat until a depth of more than 200 km. If Eq. 1 is applied to these two regions, the estimated difference in elevation, once compositional effects have been removed should be about 1,600 m. Figure 4b (from Hyndman 2010) shows exactly that effect. Elevations for both back-arc mountain belts and cold stable areas corrected for compositional density effects are plotted against local crustal thickness. Each group of data exhibit the expected trend of increasing elevation with increasing crustal thickness, but the Cordillera elevations are consistently 1,600 m higher than stable area elevations for the same crustal thickness.

Australia

Not all variations in heat flow between provinces can be easily attributed to increases in temperature. Proterozoic Australia, for instance, has typical heat flow values $>80 \text{ mW m}^{-2}$, which is more consistent with active tectonic zones than shields or cratons. Numerous studies have attributed these high heat flow anomalies to very high crustal radioactivity (e.g., McLaren et al. 2003). Surface heat flow, q_s , can be decomposed into a radiogenic heat flow, q_r , and a sub-lithospheric heat flow, q_m ,

$$q_s = q_r + q_m \quad (5)$$

Figure 5a illustrates several geotherms expected for a set of regions with identical surface heat flow but differing upper crustal heat production. The integrated lithospheric temperatures is much lower than expected by the reference geotherm family, instead isostatically equivalent to a typical region with low surface heat flow (Fig. 5b). In Fig. 3, a typical partitioning of surface heat flow between a radiogenic upper crustal component (40%) and a basal component (60%) is assumed. If this model is reconsidered to allow for variations in partitioning fraction, the surface heat flow and adjusted elevation plot (Fig. 5c) can be used to identify regions of anomalous radioactivity or sub-lithospheric heat flow. Hasterok and Gard (2016) used thermal isostasy in this manner to estimate the heat production variations within the Australian continent (Fig. 5c).

Isostasy, Thermal, Fig. 4 Thermal isostasy case study for North America Cordillera (after Hyndman 2010). (a) Temperature-depth plot for the northern Cordillera in comparison to the adjacent craton. Shaded regions in the mantle are general results from tomography; solid dots are temperature-depth loci from xenolith studies (see Hyndman 2010 for details). (b) Elevation adjusted for composition (density) versus crustal thickness (Table 3 of Hasterok and Chapman 2007b) for the hot Cordillera and cold stable areas of North America. The ~1.6 km elevation difference can be explained by thermal isostasy using Eq. 1

The decomposition method can also aid interpretation of Australian non-thermal isostatic variations. Some regions sit outside the bounds of allowable heat flow–adjusted elevation pairs which indicate a violation of the basic model (Fig. 5c). The three provinces that sit outside this region in Australia include the Pilbara Craton, Yilgarn Craton, and the Albany-Fraser belt (a reworked portion of the Yilgarn Craton). The

Isostasy, Thermal, Fig. 5 Decomposition of surface heat flow using thermal isostasy. (a) A demonstration of radiogenic effect on geotherms with the same surface heat flow and differing upper crustal heat production. (b) The differences in geotherms lead to elevation anomalies with respect to the reference thermal isostatic curve. (c) Case study of Australian heat flow and elevation (after Hasterok and Gard 2016) used to estimate radiogenic and mantle heat flow contributions to the surface heat flow. The sub-horizontal contours are lines of constant mantle heat flow whereas the sub-vertical contours are lines of constant radiogenic heat flow. The individual geological provinces separate into three

distinct sets, one with typical ranges of radioactivity and mantle heat flow when compared with North America, a second set of provinces with anomalously low elevation/high surface heat flow consistent with high radiogenic heat flow, and a third set outside the thermal bounds allowable by the model—a consequence of low-density Archean lithospheric roots. The error bars on the individual provinces have been removed to emphasize the background contours. The geotherms used to compute these models have been updated, but the thermal elevation, in Eq. 1, and the process of elevation adjustment are the same.

lithospheric mantle beneath these regions are often assumed to be depleted – compositionally buoyant – Archean lithosphere, violating the thermal isostatic model that only includes compositional adjustment for crustal buoyancy.

Thermal Isostasy on Terrestrial Planets

Venus and Mars also have convecting mantles beneath rigid lithosphere and presumably have significant variations in heat flow across their surfaces. Indeed, volcanism on Mars and Venus may be plume-related, but the cooling of the lithosphere following volcanic periods may result in significant temporal changes in topography. Cooling may be responsible for anomalies in ancient coastline elevations observed on Mars today (Ruiz et al. 2004).

Summary

Thermal isostasy, that part of isostasy traceable to density differences being caused by temperature differences and thermal expansion of rock, is an important but underappreciated condition in crustal geophysics. The condition/process of thermal isostasy received much attention in oceanic regions with the discovery of plate tectonics and seafloor spreading. It was quickly recognized that systematic cooling of the lithosphere formed at a spreading ridge could explain the 3,000 m of seafloor subsidence away from a ridge. On continents, thermal isostasy effects are obscured by compositional isostasy, principally crustal thickness, which produces over 3,000 m of elevation effects. Recent analyses, however, have developed

methods to adjust elevations for compositional effects. When those adjustments are made, there is a clear trend of increasing elevation of a continental province with surface heat flow – a confirmation of thermal isostasy. The magnitude of elevation differences between hot and cold continental regions is also about 3,000 m, comparable to thermal isostasy effects in marine areas. An excellent example of thermal isostasy effects is drawn from the North American Cordillera where Airy isostasy is unable to explain the elevation of the Cordillera terrains relative to stable shield areas. Instead, the hot upper mantle associated with current or recent back-arc activity, conveniently explains the 1,600 m of elevation difference that is observed.

KTB Depth Laboratory: A Window into the Upper Crust

Ulrich Harms and Jochem Kück
Scientific Drilling, GFZ German Research Centre for
Geosciences, Potsdam, Germany

Definition

Depth observatory or *depth laboratory* is an up to several kilometer-deep borehole or underground facility enabling observations of geophysical, geological, mineralogical, geochemical, and biological phenomena in the deep Earth. It is equipped with various sensors allowing for long-term data acquisition at crustal depth level.

KTB Kontinentales Tiefbohrprogramm der Bundesrepublik Deutschland was the Continental Deep Drilling Program of the Federal Republic of Germany with two, 4,000 m and 9,101-m-deep, boreholes drilled during the years 1987–1994.

Borehole monitoring is either the systematic direct collection of physical, chemical, rock mechanical and biological data from formations penetrated by boreholes thus covering various geological timescales or the indirect observation of information from greater depth, e.g., through elastic (seismic) waves. Installations of downhole instruments and subsequent data transmission to data centers for further processing are either permanent, e.g., cemented in place, or retrievable at the end of the observation period.

Scientific drilling encompasses an Earth science research program that utilizes drilling machines to produce a deep well, retrieve samples and acquire data from depth to gain novel scientific insights.

Introduction

Long-lasting and successful international scientific drilling projects are not only striving to provide direct access to the

deep underground for geoscientific research purposes but also to monitor in situ physical, chemical, and rock mechanical properties over prolonged time periods to understand the dynamics and processes inside the Earth. One of the paramount examples of the utilization of very deep research boreholes is the two 4- and 9.1-km-deep wells of the Continental Deep Drilling Program of Germany, in short KTB (Fig. 1). These wells have been drilled not only to understand the complex geological terrane structure of Central Europe and its related physical and thermoelastic properties but also to utilize them as windows into the deep underground for monitoring purposes. After 25 years of operating the KTB Depth Laboratory (KTB-DL) with still ongoing monitoring and testing activities, an assessment of possibilities and challenges for utilizing boreholes for Earth science is timely.

Scientific Background

The KTB project is based on a German Earth science community effort that started in 1978. Embedded in the framework of the International Lithosphere Program, research was focused on the continental crust through deep geophysical sounding and direct access through deep drilling. The German Federal Ministry for Research and Technology granted funding for KTB in 1982 with the objective to create a window into the upper crust of Central Europe. Research started with a 2-year preparatory phase including comparative geoscientific studies at five locations in West Germany and project studies for a deep well drilling program. Data gained and geological hypothesis advanced in this phase then resulted in a decision for a more detailed site survey at two locations, namely, the Upper Palatine (Oberpfalz) and the Black Forest (Schwarzwald). Studies at both locations, including drilling of several shallow boreholes, were executed and compiled from 1984 to 1986 and finally discussed in 1986, leading to a decision for the Upper Palatine site near the town of Windischeschenbach, Eastern Bavaria, SE Germany.

KTB Depth Laboratory: A Window into the Upper Crust, Fig. 1 Aerial view of the KTB-DL site with the KTB-VB pilot hole (upper left corner), KTB-HB main hole below the drill rig (foreground),

the former field lab in the main building behind the rig. The logging installations are within the orange circles

The first operational phase lasted from 1987 to 1990 with drilling of the 4,000.1-m-deep KTB-VB pilot hole, followed by a 1-year long phase to conduct measurements, testing, and evaluation, resulting in research concepts and a detailed engineering and management plan for the KTB-HB main borehole. Following this multiphase approach, the ultradeep KTB-HB (9,101 m) was then drilled from 1990 to 1994. Drilling, coring, and downhole logging of the deep KTB-HB (Figs. 2 and 3) required extensive and detailed technical planning and key technology developments. The two most outstanding advances were a fully automated drill pipe handling system reducing trip times about half and the vertical drilling systems providing an almost vertical borehole path to drastically minimize drill string friction. Both technologies, pipe handler and steering systems, have since become standards in deep drilling (Engeser 1996).

Ultradeep borehole measuring necessitated a wire line downhole logging system capable of safely handling depths beyond 8 km. This was achieved by installing a cable-friendly custom-made friction winch between the drum winch and the borehole and by running deep logs in tapered cable mode: a 1–2 km long, lightweight, HT temperature-resistant cable at

bottom and the long, heavy, and strong cable above (Kück et al. 2020).

The finalization phase in 1995 comprised the dismantling of most components of the drilling facilities, except for the logging equipment and the 80-m-high drill rig itself. Data evaluation, documentation, publication, and administrative phaseout completed this phase. In the following years, the two fully accessible, cased, and cemented deep wells were prepared as a deep crustal laboratory (KTB-DL) with concrete pads around the wells and a complete logging infrastructure including office and workshop space (Fig. 1). From 1996 on, the two KTB wells with logging and testing infrastructure were operated by the GFZ German Research Centre for Geosciences as depth laboratory. During the first 10 years, more than 250 wire line operations were performed at the KTB-DL, resulting in more than 1,000 km of logging runs. The establishment of a KTB-DL was an indispensable part of the overall KTB concept from the very beginning, because only long-term observations (months to years) allow for investigations of temporally varying processes under natural in situ conditions years after all drilling related disturbances have decayed. Such a borehole lab enables carrying out even

KTB Depth Laboratory: A Window into the Upper Crust, Fig. 2 Overview of the main activities in the KTB-DL since its start in 1996; blue = scientific experiments, green = technical activities,

insert: drilling progress chart of the KTB main hole showing delays during technical challenges below 6760 m depth

very long experiments at far lower costs compared to the very high daily costs of an active drilling.

The key scientific objectives of the KTB as defined already in 1983 (Emmermann and Lauterjung 1997) were:

1. To improve the understanding of the geological structure and evolution of the Central European Earth's crust
2. To study, sample, and monitor the geophysical structures and heterogeneities at depth and to compare them with results from surface investigations
3. To shed new light on the fluid system at depth, its pathways, and its influence on geological processes such as metamorphism
4. To determine the upper crustal temperatures, the geothermal gradient, and the crustal heat flow
5. To obtain data on stress and strain in the upper crust and better understand earthquake nucleation and propagation
6. To establish a "deep crustal laboratory" and allow for long-term observations at depth

These targets were complemented by a large number of specific science goals as defined during the course of this long-lasting project by the various Earth science disciplines

involved. The overarching goal was to conduct basic geoscientific research on the physical and chemical conditions in the deeper continental crust and the acting processes aiming to provide new insight into the structure, the dynamics, and the evolution of an intracontinental crustal area. The different research fields directed their efforts to the verification of fundamental concepts in Earth sciences. One key example was the transition from brittle to ductile deformation in a temperature range from 250 °C to 300 °C where a fundamental change in rock parameters was expected to occur (Brudy et al. 1997). Others such as the proof of several kilometer-wide networks of permeable fractures in the deeper crust and the related temperature profile and heat flow are shown in Emmermann and Lauterjung (1997) and detailed references therein.

KTB Data Infrastructure

The utilization of the KTB boreholes as deep laboratory is based on the complex digital data record available for the site. Cores, cuttings, and fluids were regularly sampled in short intervals and are mostly still available to interested science parties.

**KTB Depth Laboratory:
A Window into the Upper
Crust, Fig. 3** Drilling and casing
scheme of the KTB boreholes
showing the current KTB Depth
Laboratory layout

Sample materials were investigated in great detail for a wealth of critical parameters in mineralogy, geochemistry, petrophysics, and geomechanics. These data and complementing downhole logging data, borehole tests, and surface geophysics including deep geophysical sounding and their joint

interpretation have been published and are digitally available for download. The data set was mainly acquired during the drilling phase in the KTB field laboratory (Emmertmann and Lauterjung 1997). KTB samples and data served and still serve to publish a large number of scientific papers. This wealth of

information available makes the cuboid around KTB with its size of about 10 km depth times several kilometers lateral extension one of the best explored crystalline basement blocks on Earth. The complete digital data sets including metadata and the related links to all published KTB reports are available from Kück et al. (2020).

KTB Depth Laboratory Utilization

The KTB-DL layout with two deep wells at just 200 m distance is shown in detail in Fig. 3, while the supporting surface infrastructure surrounding of the boreholes (downhole logging tools, winches, cables, workshops, offices, etc.) is indicated in Fig. 1. The main well is still accessible down to 6,700 m with c. 200 mm diameter instruments ($T_{\max} = 190^\circ\text{C}$ and $p_{\max} = 66\text{ MPa}$), while the pilot well is still fully accessible down to 3,970 m with 90 mm diameter devices (at $T_{\max}/p_{\max}$ of $115^\circ\text{C}/20\text{ MPa}$). This setup allowed for experiments and tests over more than two decades. Over the first 5 years, more than 200 weeks of experiments were performed in the wells, while over the last 5 years (2013–2018), about 60 weeks of operations happened on site. In summary all post-drilling activities at the KTB-DL can be ordered into four categories:

Geoscientific Experiments

During the first KTB-DL phase from 1996 to 2006, the KTB holes were intensely used with an uninterrupted sequence of scientific experiments that were planned ahead already during the KTB drilling time. Experiments carried out investigated eight main research areas: deep temperature gradient, gravity field (deepest gravity meter survey), tidal effects (frac breathing at 4 km) (Schulze et al. 2000), deep magnetic survey through steel casing, seismic imaging in crystalline rocks/deepest VSP/MSP (Rabbel et al. 2004), seismology (seismometer at 4 km for almost 2 years), rheology of the Earth's crust/fracture propagation from brittle to ductile below 9 km (Bohnhoff et al. 2004), and fluid transport. The duration of these experiments varied between a few weeks and 4 years. More than 200 scientists and technicians from 22 institutes and companies worked at the KTB-DL and the surrounding area during this time. The longest experiment lasting from 2002 to 2005 was a pumping and injection test, each part one and a half year long with the aim to investigate the fracture network intersected by the pilot hole at c. 3,995 m and the natural rock fluids therein. An amount of $23,000\text{ m}^3$ was produced from the well, and later almost $85,000\text{ m}^3$ of freshwater was injected into the crystalline rock (Fig. 2). Key results such as the far-reaching fluid pathways at depth with high fracture permeabilities have been published in a special volume of *Geofluids* (Erzinger and Stober 2005) and by Kümpel (2006).

Test and Calibration of New and Existing Instruments, Methods, and Installations

Since 2006 the boreholes are used mainly by GFZ and other research institutes for verification and testing of new and experimental instruments and methods as well as for technical works such as tool testing and equipment preparation before and after campaigns elsewhere. In the framework of GFZ's and other research institutes' downhole tool development programs and the ongoing utilizations of geophysical borehole sondes, the wells are regularly used for performance tests and to calibrate instruments, e.g., XRF-density/elements sonde, memory logging-while-tripping sondes, borehole heat exchange reactor, and active seismic prediction sonde. Future experiments will target at fracture-fluid systems in deeper regions ($>6,000\text{ m}$) and the deep biosphere in the formation fluid filled and since many years undisturbed 4-km-deep pilot hole with an open hole temperature at 110°C .

Commercial Utilization of the KTB Wells

Aside from the academic utilization of the KTB-DL, the holes are also used by a number of companies to test or verify new downhole methods, tools, cables, and winches under in situ conditions (temperature, pressure, in-hole cable length). Logging service companies frequently use the deep well to season new logging cables (reduce cable torque) before using them in actual logging jobs.

Outreach and Education

Based on the public outreach facility installed during drilling, a vibrant environmental and geoscientific education center with an on-site museum, the "GEO-Zentrum an der KTB," has been established at the KTB site since 1998. It is running continuously with communal and local state support as well as European Union funding. The number of visitors as of 2018 is in the range of 25,000 per year. The center serves as KTB museum with the KTB drill rig as landmark and focuses in addition on Earth and environmental education for teachers and school classes. It is also used for academic education such as for courses in the framework of the International Continental Scientific Drilling Program (ICDP).

The access to the KTB wells with conditions of utilization has been detailed by Harms and Kück (2016) at <http://www.gfz-potsdam.de/en/section/geomechanics-and-rheology/infrastructure/ktb-deep-crustal-lab/>.

Long-Term Utilization of a Deep Borehole Site

The majority of scientific drilling projects worldwide as well as commercial drillings have strict legal obligations concerning well completion and abandonment. This commonly requires closing the borehole safely by cutting casings, cementing the well, and other procedures to ensure hydraulic and gas sealing of

intersected reservoirs. For long-term use of boreholes, it is therefore necessary that a company or institute has to take responsibility for safety and final borehole closure and to commit to its enduring mining law responsibility. In the case of the KTB-DL the GFZ German Research Centre for Geosciences is legally responsible.

A crucial lifetime determining factor of borehole observatories is the long-term accessibility of the borehole, both logistically at surface and inside the well due to borehole wall instability, together with the availability of funds to work over collapsed hole sections. Only few deep drill holes stay stable over many years, and even a steel casing is in danger to be damaged and deformed by failing rock in a strong triaxial stress field. In general, the deeper the hole is, the higher is the risk of collapse which has to be expected.

Unsurpassed until today is the Kola Superdeep SG-3 in NW Russia with more than 12 km depth which had an observatory phase after the end of the drilling operations since 1994. It offered 8,500 m of the mainly cased well (Popov et al. 1999) also for international utilization. Despite highly qualified and experienced experts, the difficult and uncertain conditions after end of the Soviet Union led to an insignificant utilization and withdrawal of governmental support. The facilities were abandoned in the year 2008, and the infrastructure deteriorated soon after.

Fortunately, other borehole laboratories have derived from scientific drilling projects in various geological environments because the drilled rocks proved to be stable and bearing no special risks. Organizations like geological surveys, research institutes, or universities committed to remain responsible, to maintain sites, and to offer access to wells for protracted periods. Examples are the 2,500-m-deep Outokumpu borehole laboratory OKU-1 in Finland since 2006, the 2,500-m-deep COSC-1 underground lab near Åre in Sweden since 2014, and the 3,000-m-deep KFD1 hole of the Koyna drilling project in India since 2017, all supported by the ICDP. More depth laboratories can be expected in the coming years because long-term monitoring has become an inherent component of deep scientific drilling projects.

Summary

The KTB-DL after 25 years in operation continues to offer deep access to the upper crystalline crust. The infrastructure available and the stable conditions of the vertical 9191-m-deep KTB main hole (accessible to 6,700 m) and the 4000-m-deep KTB pilot hole (open hole section from 3,850 to 3,970 m) at only 200 m lateral distance invite for both ultra-deep geoscientific experiments and for technical use as test bed. The KTB-DL was used in the first 10 years after drilling primarily for further scientific investigations of fluids and seismicity while tool development and testing purposes prevail in the experiments in the recent past. Multi-purpose

utilization including science, commercial use and education and outreach as well as stable funding conditions have ensured 25 years of lifetime of the KTB wells. New depth laboratories and observatories have emerged in the past 10 years and more can be expected from upcoming deep scientific drilling projects.

Continental margin; Continental shelf; Extended continental margin; Extended continental shelf

Definition

The legal continental shelf comprises the submerged prolongation of the land mass of a State beyond 200 nautical miles (M) from the territorial sea baselines, consisting of the seabed and subsoil of the shelf, the slope, and the rise. Formulae to determine the outer limits of the legal continental shelf are in Article 76 of the United Nations Convention on the Law of the Sea (UNCLOS). Application of the Article 76 definition frequently turns on an understanding of the geology, geophysical structure, and tectonic evolution of the sea floor.

Introduction

A State has exclusive rights over the seabed resources of its legal continental shelf as the natural prolongation of its land territory. The assertion of those rights is an inherent entitlement, not a claim.

In 1982 UNCLOS imposed a legal framework on the scientific concept of the continental shelf, creating a clear definition of the outer limits of the legal continental shelf

and a process for international verification of those limits. These are contained in Article 76 of UNCLOS and Annex II of the Final Act of the Third United Nations Conference on the Law of the Sea (the Statement of Understanding). Under Article 76 the continental shelf is defined as extending to the outer edge of the continental margin, subject to two constraints.

Article 76 was drafted to deal with the vast majority of continental margins, but it does not adequately deal with margins characterized by a narrow and steep morphological shelf and slope and an extraordinarily extensive rise. The Statement of Understanding extends the principles of Article 76 to those margins.

Where the outer limits of the continental shelf extend beyond 200 M from the coast, a State must make a submission to the UN Commission on the Limits of the Continental Shelf (CLCS) to verify that the outer limits have been calculated correctly. The recommendations issued by the CLCS in response to States' submissions address the real world complexities of continental margins and continue to refine the understanding of the legal continental shelf and the scientific concepts that underpin it.

Defining the Outer Edge of the Continental Margin and the Limits of the Continental Shelf

Article 76 defines the continental margin to include the shelf, the slope, and the rise as the “submerged prolongation of the land mass” distinct from the “deep ocean floor.” The outer edge of the continental margin is determined through the application of two formulae, both calculated from the foot of the continental slope (Fig. 1). The outer edge of the margin lies at points 60 M from the foot of the slope or where the thickness of sediment is 1% of the distance from the foot of the slope. In the absence of evidence to the contrary, the foot of the slope is identified at the point of maximum change in seafloor gradient.

Legal Continental Shelf: Geology, Geophysics, and Tectonics, Fig. 1 Cartoon showing a hypothetical continental margin, summarizing the formulae and constraints described in Article 76 that determine the outer limits of the continental shelf. (Modified from Kapoor and Kerr 1986)

Article 76 also constrains the legal continental shelf to no more than 350 M from the coast or 100 M from the 2500 m isobath, whichever is greatest. On margins with expansive, relatively shallow slopes the 2,500 m + 100 M constraint can lie seaward of the 350 M line. Significantly, the 2,500 m + 100 M constraint applies to “submarine elevations that are natural components of the margin” but does not apply to “submarine ridges” (limiting these to 350 M). The distinction between “submarine elevations” and “submarine ridges” remains both conceptually and analytically difficult. Although the CLCS Technical Guidelines (1999) reveal general principles that are considered, each feature must be assessed individually in terms of its morphological, geological, and tectonic continuity (Brekke and Symonds 2011).

Applying the Article 76 definition requires four steps (Fig. 2): (1) the outer edge of the continental margin is identified using the two formulae; (2) the two constraint lines are determined; (3) the most seaward constraint line is applied; and (4) the resulting line composed of formulae and/or constraint lines is connected by lines up to 60 M long (Wood et al. 2011). These steps are described in the CLCS Technical Guidelines (1999).

Margins with a narrow morphological shelf, steep slope, and a very extensive rise may meet the criteria under the

Statement of Understanding. The Statement of Understanding has four elements that identify continental margins to which it applies. For States that meet its criteria, the Statement of Understanding, in conjunction with the CLCS Technical Guidelines (1999), defines the outer limits of the continental shelf at points where the sediment thickness is at least 1 km.

Prolongation of the Land Mass

The concept of the submerged (or natural) prolongation of the land mass is central to the definition of the legal continental shelf. Establishing where prolongation occurs and the nature of that prolongation are of primary importance because they determine (a) whether a legal continental shelf exists and (b) how far it extends beyond 200 M (Wood et al. 2011).

Natural prolongation has three aspects (Wood et al. 2011):

- Morphologic – the seafloor shape is a continuation of the land mass morphology.
- Geologic – the rocks beneath the seafloor are the same as, or related to, those of the land mass.
- Tectonic – the rocks beneath the seafloor share their history with those of the land mass.

Legal Continental Shelf: Geology, Geophysics, and Tectonics, Fig. 2 The four steps for establishing the outer limits of the continental shelf. (From Wood et al. 2011)

The transition from land mass to deep ocean floor is the result of the composition and density of the rocks beneath the seafloor, the geological processes that form and shape them, and the tectonic forces that act on them (Wood et al. 2011). The morphological transition is relatively simple on many margins, with a shelf dipping gently to a depth of several 100 m, a steeper slope deepening to a depth of several 1,000 m, and a gently dipping rise lying between the slope and the flat deep ocean floor (Fig. 1). Other margins have a complex morphology with ridges, seamounts, and canyons, and the transition with the deep ocean floor can be harder to recognize (Fig. 3).

Role of Geology and Tectonics

The Article 76 definition divides the Earth into land territory, the continental margin, and the deep ocean floor with its oceanic ridges. Applying that definition to a particular margin often requires complex scientific analysis. On simple margins the shelf, the slope, and the rise may be easily identified from the seafloor morphology. The primacy of seafloor morphology is reinforced by both the CLCS Technical Guidelines (1999) and subsequent CLCS recommendations. But frequently geology, geophysics, and tectonics will be important in interpreting that morphology to:

Legal Continental Shelf: Geology, Geophysics, and Tectonics, Fig. 3 (a) Foot of slope positions along Reykjanes Ridge determined from analysis of (b) multibeam data and regional tectonics. (From CLCS 2016)

- Distinguish between areas that are part of the continental margin and those that are part of the deep ocean floor
- Distinguish between “submarine ridges” and “submarine elevations that are natural components of the margin”
- Clarify the location of the foot of the continental slope

The role of geology and tectonics in the application of Article 76 is demonstrated by examples from the recommendations on the submissions by Iceland, Ascension Island (the United Kingdom), Bouvetøya and Shaka Ridge (Norway), Ogasawara Composite High (Japan), and the Kerguelan Plateau (Australia).

Iceland is the product of voluminous volcanism related to the interaction of a mantle hotspot with a seafloor spreading ridge. Because its origin is similar to that of the volcanism that forms the deep ocean floor, geologically it is difficult to identify the boundary of the continental margin. In its recommendations the CLCS concluded that hotspot-ridge interaction had significantly changed the seafloor spreading process and the morphology of parts of the Reykjanes Ridge (CLCS 2016). It therefore considered that the region defined by the Iceland hotspot interaction with the seafloor spreading process is part of the continental margin of Iceland for the purposes of Article 76.

Even given this criterion for identifying the outer limits of the continental margin, finding those limits is not

straightforward. Figure 3a shows the foot of slope points along the Reykjanes Ridge that were accepted by the CLCS. It is apparent that their choice is not based entirely on morphology but also on identification of the V-shaped seafloor region formed by hotspot activity (Fig. 3b). Significantly, the CLCS could not agree on whether the continental margin is a “submarine ridge” or a “submarine elevation” for the purposes of Article 76.

A similar argument was used by the United Kingdom for prolongation from Ascension Island. The United Kingdom submitted that Ascension Island is an integral component of the Mid-Atlantic Ridge and its natural prolongation therefore extends along the ridge. The CLCS agreed that islands surmounting ridges rising from the deep ocean floor are entitled to a legal continental shelf. But it determined that the rugged seafloor surrounding the Ascension Island volcanic edifice is part of the deep ocean floor and there is no morphological feature in the vicinity of Ascension Island that could be characterized as continental margin extending beyond 200 M (CLCS 2010).

In summary, Iceland was able to demonstrate that the volcanic processes that formed the land mass affected areas of the surrounding seafloor so that they are morphologically and geologically distinct from the adjacent deep ocean floor. Iceland could therefore show the continental margin extended beyond 200 M. Ascension Island, on the other hand, could not

identify a geological distinction between the volcanic edifice on which the island sits and the Mid-Atlantic Ridge.

Similar to Ascension Island, Bouvetøya is a volcanic island on the Southwest Indian Ridge in the South Atlantic, a seafloor spreading ridge. Bouvetøya and the elevated area of seafloor extending northeast from it to the eastern end of Shaka Ridge are interpreted to have formed by hotspot related volcanism.

On the basis of seafloor morphology and the geochemistry of the basement rocks, the CLCS agreed that there was natural prolongation of Bouvetøya to the eastern end of Shaka Ridge (CLCS 2019). In addition, the CLCS relied on geochemical analysis to conclude that the Shaka Ridge is a “submarine elevation” that forms a natural part of the Bouvetøya margin, distinct from the oceanic basalts of the deep ocean floor of the Southwest Indian Ridge.

Geology and tectonics also played an interesting role in determining the outer limits of Japan’s continental shelf around the Ogasawara Composite High, on the eastern flank of the Izu-Ogasawara Arc southeast of the islands of Japan. The Ogasawara Composite High is composed of several east-west trending seamounts, and straddles an active subduction trench and volcanic arc.

The presence of an active subduction trench could be considered a fundamental obstacle to establishing prolongation. But the CLCS identified an elevated morphological saddle across the subduction trench, which it considered sufficient to demonstrate prolongation to the high (CLCS 2012). This was reinforced by its acceptance that, based on the presence of thrust faulting, the western part of the high had been accreted to the Izu-Ogasawara Arc, and thus is a “submarine elevation” forming a natural part of the Japanese margin. The eastern part of the high, by contrast, had not been accreted and was concluded by the CLCS to be a “submarine ridge.”

In Australia’s continental shelf submission on the Kerguelan Plateau region, geology was used to distinguish between elements of the plateau region which are “submarine elevations” and those which are “submarine ridges.”

Heard and MacDonald Islands are embedded within the late Cretaceous magmatic crust of the Central Kerguelan Plateau. These basement rocks and those of the morphologically connected Southern Kerguelan Plateau show affinity with continental crust based on geochemical evidence. The CLCS therefore agreed that the Central and Southern Kerguelan Plateau regions are “submarine elevations” and natural components of the continental margin of Heard and MacDonald Islands (CLCS 2008).

However, the Commission decided that there is insufficient data to establish the geological origin of Williams Ridge, a ridge extending southeast from the Central Kerguelan Plateau. Therefore, even though it is morphologically part of the margin, the CLCS considered it is a “submarine ridge,” not a natural component of the continental margin.

Summary

The definition of the legal continental shelf in Article 76 enables States to define the outer limits of the continental shelf with geographic precision. The elements of the definition, and the discipline imposed by the requirement to submit outer limits to the CLCS for review, have required States to study the geology, geophysical structure, and tectonic evolution of the continental margin in new detail. This is particularly important for complex margins where the shelf, slope, and the rise cannot be easily identified from the seafloor morphology, and there is uncertainty in distinguishing the transition from land mass to deep ocean floor.

The examples from Iceland, Ascension Island, Bouvetøya and Shaka Ridge, the Ogasawara Composite High, and the Kerguelan Plateau show the value of tectonic and geological evidence when applying the Article 76 definition. Although seafloor morphology remains the primary evidence, there is in many cases a proven need to consider a range of geological, geochemical, and geophysical evidence to determine the outer limits of the legal continental shelf.

Lithosphere, Continental

David E. James

Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC, USA

Definition and Introduction

The continental lithosphere consists of the continental crust and, typically, some nonconvecting part of the underlying upper mantle (Fig. 1). In plate tectonics terms, the continental lithosphere is part of the rigid outer rind of the Earth, which is segmented into several major plates. The cold lithosphere lies atop a hotter, more mobile (low strength) asthenosphere. In this context, oceanic lithosphere for the most part obeys comparatively simple thermal models, with the boundary

between lithosphere and asthenosphere represented by an isotherm marking the transition in mantle peridotite between elastic and ductile behavior (but see ► [“Lithosphere, Oceanic”](#) for the growing list of complications). By contrast, the continental lithosphere is heterogeneous and its structure highly variable. That contrast reflects the fact that oceanic lithosphere is formed in much the same way worldwide and that it is continually recycled into the interior of the Earth via the plate tectonic “conveyor belt.” Continental lithosphere, on the other hand, is generally too buoyant to be subducted, although an increasing number of instances have been reported in which parts of continental lithospheric mantle show evidence of gravitational instability, forming “drips” where lithosphere delaminates and sinks into the deeper mantle (Zandt et al. 2004). The detachment of continental mantle from the crust in such circumstances may be an important factor in intraplate deformation and volcanism (Carlson et al. 2005). Thus, while no known oceanic lithosphere is older than about 200 my, the continental lithosphere has evolved over billions of years, one consequence of which is that it is seen today as the resulting collage of many superimposed tectonic events, including rifting, subduction, continental collision, accretion, and hot spot magmatism, that recur repeatedly over geologic time.

The study of continental lithosphere has been revolutionized over the past two decades with the advent of portable

Lithosphere, Continental,

Fig. 1 Schematic cross section showing transition from oceanic lithosphere to younger continental lithosphere and into the thick, cratonic lithosphere (tectosphere) beneath the ancient continental nuclei. Melts rising from depth ascent through relatively thin oceanic and young continental lithosphere to produce volcanoes at the surface, whereas thick tectosphere acts as a barrier to melts percolating from depth, requiring evolved, volatile-rich kimberlitic magmas to bore a conduit through the mantle to the surface

broadband seismology. Passive array experiments (see ► [“Seismological Networks”](#)) have made it possible to obtain high-resolution images of deep lithospheric structures beneath every continent (James 2007). The greatest concentration of high-density broadband deployments has been in western North America, Europe, and Asia, with large-scale experiments also in Africa, Central and South America, and Australia. Within the USA, the Transportable Array of the national EarthScope project has already resulted (at the time of this writing) in uniformly high-resolution seismic imaging of the mantle beneath the western half of the nation. The lithosphere so revealed consists of a collage of overlapping structures produced by ongoing subduction, trench migration, ridge override, regional extension, mantle upwellings and volcanism, and lithospheric delamination. In some tectonically active regions, a thin crust is the only lithosphere remaining intact (Carlson et al. 2005). This complex and disrupted lithosphere is in marked contrast to that of stable cratonic regions, including the continental nuclei of north-central North America, western Australia, and southern Africa. The cratons of southern Africa are perhaps the best studied of the Archean cratons of the world, where results from large-scale passive array experiments show that lithospheric roots as deep as 250 km or more underlie the undisturbed parts of the cratons (James and Fouch 2002; Ritsema and van Heijst 2000).

Despite remarkable progress in imaging the continental lithosphere over the past 2 decades, a precise definition of continental lithosphere remains elusive. No single definition of continental lithosphere can be made to fit all circumstances. Particularly controversial is the definition of what constitutes the base of the lithosphere. Many definitions of continental lithosphere appear in the literature – seismological, mechanical, rheological, thermal, and compositional. Depending on one’s view, the continental lithosphere may be a *mechanical boundary layer*, a *thermal boundary layer*, or a *chemical boundary layer*. In the remainder of this entry, we shall explore these various concepts in some detail. Our goal here is to describe the continental lithosphere in terms of global Earth structure, plate tectonics, and the long-term evolution of the continents. By this view, the continental lithosphere is envisaged to be a long-lived plate tectonic unit, consisting both of continental crust and, typically, a very significant mantle “keel” that is attached to and translates with the continent. In this sense, it is seen as a stable component of the continent and does not participate in the convective processes of the deeper dynamic mantle.

Mechanical Models

A simple expression of the lithosphere is *elastic thickness*. While rarely used to describe continental lithospheric in a

geologic or structural sense, elastic thickness is a useful concept in that it models the mechanical response of the lithosphere as an elastic plate overlying a weak (asthenospheric) substrate. As discussed in detail elsewhere in this volume (see ► [“Lithosphere, Mechanical Properties”](#)), the elastic thickness of the lithosphere may be determined through topographic response to surface loads (such as volcanoes), the relationship between topography and Bouguer gravity anomalies, or the shape of depositional surfaces in basins. The thickness of elastic lithosphere so determined is rarely as much as 100 km and in areas of extension or hotspot activity may be less even than crustal thickness. The elastic thickness of the continents is chiefly controlled by the thermal state of the lithosphere (see ► [“Lithosphere, Mechanical Properties”](#)). As Forsyth (1989) points out, however, the apparent elastic thickness is also affected by the state of stress and the rheological stratification in the crust and mantle, so mechanical thickness may not bear a simple relationship to a particular isotherm.

One important aspect of the mechanical structure of the continental lithosphere as it relates to lithospheric evolution is the large decrease in strength of crustal rocks in the deep crust. The steep geothermal gradient in the crust produces increasing ductility of crustal rocks with depth. The brittle zone in tectonic areas typically extends only to about 15 km, below which the rocks deform plastically. The topmost part of the underlying mantle, however, is relatively much stronger as temperatures there are still far from the melting point of mantle rocks. Thus, it is widely posited that there is a zone of weak lower crust sandwiched between strong upper crust and strong upper mantle, creating a possible zone of crust–mantle decoupling (see ► [“Lithosphere, Mechanical Properties”](#)).

While the flexural lithosphere is a useful *mechanical* concept, it fails as a plate tectonic description of lithosphere. In many tectonic regions, the flexural lithosphere is not even as thick as the continental crust. As low-density sialic crust is not easily subducted into the mantle, it must persist as the primary long-lived component of continental lithosphere. From the perspective of plate tectonics, it may be argued that the full definition of the lithosphere should account both for the long-term structural coherence of continental plates and the impact of asthenospheric processes that affect either the formation or the removal of lithospheric mantle beneath the crust.

Thermal Models

A convenient definition for *thermal lithosphere*, or the thermal boundary layer, is the outer layer of the Earth in which heat transfer is dominated by conduction (see ► [“Heat Flow, Continental”](#) and ► [“Lithosphere, Continental: Thermal Structure”](#)). Thus, the stronger lithosphere acts as a barrier

to thermally induced buoyancy forces that drive convective heat transfer in the underlying asthenosphere (Morgan 1984). In the case of the oceanic lithosphere, this conductively cooled layer of the Earth is thought to have finite thickness (i.e., the lithosphere ceases to undergo thermal contraction as it ages beyond about 80 Ma, implying that heat is supplied to the lithosphere from the underlying asthenosphere) (see ► “Lithosphere, Oceanic” and ► “Lithosphere, Oceanic: Thermal Structure”). For the continents, the situation is far more complex. The continental lithosphere does not undergo simple monotonic cooling, but may be subjected to repeated episodes of thermal or tectonic disturbances. Thus, superimposed upon the geological age of the lithosphere is the thermal or tectonic age of the lithosphere, factors that have led to significant compositional heterogeneity in both crust and lithospheric mantle.

We consider first the thickness of the thermal boundary layer beneath the stable cratonic cores of the continents. Here, the lithosphere is both at its thickest and its strongest. If the effective viscosity of the asthenosphere beneath the cratonic lithosphere is taken to be about 10^{21} Pa s, based upon glacial unloading and gravity/topography correlations (see ► “Mantle Viscosity”), it implies a temperature of transition from conductive to convective heat transfer of about 1300–1400 °C for typical mantle compositions (Morgan 1984). If crustal heat production is taken into account, the thickness of the thermal lithosphere of the stable continental cratons as calculated from surface heat flow may range from about 90 to 220 km (Rudnick et al. 1998).

The lithospheric thickness obtained by thermal modeling depends upon other factors, the most important of which is the composition, including volatile content, of the subcrustal mantle. If the continental lithospheric mantle consists of low-density peridotite depleted of its low-melting basaltic fraction and devolatilized over time due to metamorphic and magmatic events (see discussion below), the continental mantle will be less dense and substantially more refractory than the rest of the mantle. The chemical boundary layer represented by this depleted subcontinental mantle peridotite may stabilize the continental mantle root against thermal disruption to depths below the thermal boundary layer (Jordan 1978, 1981).

Tectono-thermal events, such as those that are widespread across the western USA, will have the effect of thinning the existing lithosphere. Regions where prior thermal disturbances have occurred, therefore, may be more prone to reactivation, whereas stable cratons, particularly those buffered by bordering Proterozoic mobile belts as in southern Africa, should be comparatively less vulnerable to thermal perturbations from the underlying asthenosphere (Pollack 1986). Tectonic reactivation seems to be particularly true of continental rifting, where repeated episodes apparently recur along the same long-lived zones of weakness. The greatly

expanded scope of tomographic studies in recent years has revealed a number of localities in which various forms of lithospheric delaminations, or “drips” appear to be occurring, including a number in the western USA (e.g., West et al. 2009; Zandt et al. 2004). Such processes suggest that lithospheric mantle beneath tectonically active areas of the continent may be thinned or removed and later regenerated. Indeed, a wide range of epeirogenic (vertical) movements within continental interiors have been interpreted to be due to thermal disturbances that produce lithosphere heating and thinning, followed by conductive relaxation and asymptotic thickening of the lithospheric thermal boundary layer.

Seismological/Compositional Models: Tectosphere

It is well known that average seismic velocities, especially shear velocity, are much higher under cratons than under oceanic or tectonically active areas. This was first shown by surface wave dispersion measurements and later by measurements of vertically travelling ScS phases. Sipkin and Jordan (1980) showed that ScS one-way travel-time anomalies associated with the upper mantle beneath stable continental interiors could be as large as 3.5 s (fast) relative to the upper mantle beneath the western Pacific. Moreover, the high-velocity continental paths are also associated with high Q_s , suggesting that the anomalies are due to thermal and/or compositional variations in the upper mantle (Jordan 1981). Since the early studies of Sipkin and Jordan, numerous other studies based on three-dimensional inversion of travel-time anomalies for velocity structure have been carried out regionally across the globe (see summaries in Carlson et al. 2005; James 2007). The results nearly all show that regional velocity contrasts, even between provinces entirely within the continents, extend to at least 200–250 km (James 2007).

The notion of a long-lived thermochemical boundary layer in the upper mantle beneath vast regions of Precambrian crust raised many difficult questions as to how they formed and how they survived over geologic time and to a significant extent these questions remain only partially answered. There is general agreement, however, that the longevity and stability of ancient cratonic roots must be due, at least in part, to a combination of factors, primarily compositional buoyancy and strength and secondarily buffering of cratons by marginal Proterozoic mobile belts. The concept of a stabilizing chemical boundary layer is at the heart of the *temperature-depletion compensation* hypothesis laid out by Jordan in an important series of papers on the continental *tectosphere* (see Jordan (1981) for references) and discussed in some detail below. The term tectosphere was introduced by Jordan in an attempt to circumvent some of the difficulties associated with the conflicting definitions of lithosphere alluded to above. It is

a particularly convenient concept for understanding those seismological and petrological/geochemical aspects of deep continental structure that appear to indicate continent-ocean heterogeneity to depths of at least 200 km, and perhaps considerably more.

There is a large body of knowledge about the composition of deep cratonic mantle from the study of xenoliths that have been carried to the surface in explosive volcanic pipes. The development of accurate mineralogical geothermometers and geobarometers, which allow the equilibrium depth and temperature of xenolith source regions to be determined, made it possible to “map” xenolith compositions as functions of position in the mantle. A comprehensive summary of results from the geochemical study of mantle xenoliths can be found in Carlson et al. (2005). Most of the ultramafic nodules associated with older cratonic areas are highly depleted in their basaltic melt fraction to a depth of at least 200 km and are approximately the same age as the overlying crust (Carlson et al. 2005; James et al. 2004). Depleted mantle xenoliths, which are by far the most common, are characterized by significantly lower density and higher seismic velocities than the more typical fertile suboceanic mantle (Boyd and McCallister 1976). This fact led Jordan (1981) to

postulate a thick *chemical boundary layer* for the continental tectosphere.

The effect of removing a basaltic partial melt from a fertile mantle peridotite (such as the hypothetical pyrolite of sub-oceanic mantle) is to reduce the density of the residue and to increase seismic velocities. Jordan compared densities of depleted peridotite nodules with densities of a hypothetical pyrolite composition and shows that average depleted peridotite of subcontinental mantle has a normative density about 1.3% less than that of pyrolite. This reduction in density will approximately compensate for the density contrast in a homogeneous mantle that would result from the temperature contrast of about -400° between a typical shield geotherm and the average oceanic adiabat. The model then, is based on the supposition that the lower density of the subcontinental mantle due to basalt depletion is gravitationally balanced by the density decrease in the oceanic mantle caused by a much higher geotherm, hence the expression *temperature-depletion compensation* (Fig. 2). The thickness of the chemical boundary layer is generally taken to be about 150–200 km.

The tectosphere model remains controversial. The mechanisms by which a chemical boundary layer can be built up to form a deep mantle keel beneath ancient continental crust are

Lithosphere, Continental, Fig. 2 Schematic diagram (adapted from Jordan, e.g., (Jordan 1988) with reference to previous work) showing the principal components of the isopycnic (“equal density”) hypothesis. The cold, strong lithosphere (A) extends to at least 250 km beneath the ancient cratons and migrates with the craton during plate motions. At comparable depths beneath the oceans (B), the mantle is hot, weak, and mobile. The depleted mantle peridotite that makes in the cratonic keel is

depleted in heavier constituents (e.g., Fe) and is therefore intrinsically less dense than more fertile oceanic mantle at the same temperature and pressure. At the same time, the sub-cratonic mantle is colder than the suboceanic mantle so the densities are approximately equal (the “temperature-depletion compensation” model). The chemical buoyancy of the cratonic root, along with its anhydrous strength, helps stabilize it against convective disruption over geologic time

poorly understood, although there are many modes by which magma can be extracted from continental mantle over time (Carlson et al. 2005). The most difficult aspect of deep mantle roots to model, however, has been their remarkable dynamical stability over billions of years of a chemical boundary layer whose thickness varies laterally by 150 km or more (Shapiro et al. 1999). Convective instability should act to disperse and thin the zone of depleted mantle, and the fact that this does not occur appears to be due largely to the anhydrous, highly viscous, nature of the depleted mantle keel.

One aspect of lithospheric formation that may be important in some cases involves underplating of continental lithosphere by oceanic lithosphere. There is evidence, for example, that among the eclogites brought up in kimberlite pipes in Africa some may be relicts of basaltic oceanic crust emplaced beneath the continental lithosphere in Precambrian time (MacGregor and Manton 1986). The data on which this conclusion is based come primarily from measurements of oxygen isotopic ratios combined with trace element and radiogenic isotopic ratios. The oxygen isotopic ratios (low δO^{18}), in particular, are difficult to explain as originating anywhere other than in oceanic crust. Similar evidence for underplating of cratonic mantle by oceanic lithosphere has also been found in sulfide inclusions in eclogitic diamonds from southern Africa, where episodic diamond formation has been linked to the accretion of oceanic lithosphere onto early cratonic nuclei, with subsequent stabilization of the tectospheric mantle (Shirey et al. 2001).

Lithosphere–Asthenosphere Boundary

A fundamental concept of plate tectonic theory is that the cold, rigid lithospheric plates of the Earth's outer rind are decoupled from the hot, ductile underlying mantle of the convecting Earth at the lithosphere–asthenosphere boundary (LAB). The detailed nature of this global boundary, despite many years of intense study, is still very poorly known. Yet understanding the seismic and rheological character of the decoupling zone between lithosphere and asthenosphere is a critical element in understanding the dynamical interaction between the lithospheric plates moving across the surface of the globe and the convecting asthenospheric mantle beneath. While seismic studies of the LAB beneath the ocean basins show that in many cases – although by no means all – the LAB can plausibly be related to an isotherm or rheological interface, the LAB beneath continents is far more problematic, particularly beneath the stable continental interior, where the LAB has been remarkably difficult even to detect, and its specific nature remains largely unknown.

Much of the information gleaned over the past 2 decades on the velocity structure and thickness of the continental lithosphere comes from seismic tomography, which images

3-D variations in velocity distribution in the upper mantle. Where continental lithospheric mantle is present, it is seen as a higher velocity layer overlying a lower velocity asthenosphere. On the other hand, tomographic imaging, while an invaluable tool for 3-D mapping of velocity structure, provides little or no information as to the sharpness of the lithosphere–asthenosphere boundary or the velocity contrast across it. This is a significant limitation, as knowledge of the fine structure of the LAB is crucial to sorting out the competing effects of varying geothermal gradients and the presence or absence of hydrous/carbonate fluids or partial melts for decoupling the continental lithosphere from the mobile mantle beneath.

Direct approaches to determining velocity structure at the base of the lithosphere generally involve investigating the small seismic signals produced either by the *conversion* or the *reflection* of teleseismic body waves incident on the underside of the lithosphere–asthenosphere discontinuity (e.g., Rychert et al. 2005; Sacks and Snoke 1977). A converted phase is generated when some fraction of the energy of a compressional/shear wave that is obliquely incident on a velocity discontinuity in the Earth is converted to a shear/compressional wave. One widely used method, *receiver function analysis* (see ► “[Seismic, Receiver Function Technique](#)”), can effectively isolate the small signals on seismic records that represent conversions from the LAB. In principle, the waveform and amplitude of converted phases can provide detailed information about the structure (sharpness) and the velocity contrast – including the sign of the velocity contrast – across a discontinuity. Similarly, underside reflections from the LAB, which are seen on seismic records as small precursors to the large amplitude SS or PP surface reflections from distant earthquakes can be used to determine the sharpness and velocity contrast across the LAB. Unlike conversions, however, underside reflections sample substantial areas of the LAB (typically ~ 1,000 km in the case of SS phases) and, therefore, measure average regional, rather than local, structure.

Unlike most discontinuities in the Earth, the LAB represents a reversal in velocity with depth, the effect of which is to produce a converted or reflected signal with opposite polarity to that produced by a velocity increase. Results of receiver function studies of converted phases from the LAB have been decidedly mixed. An important study published in 2005 (Rychert et al. 2005) revealed a sharp LAB at a depth of about 100 km beneath northeastern USA (Fig. 3). The authors suggested on the basis of the magnitude of the negative shear-wave velocity contrast across the LAB (~5.10%) and the sharpness of the velocity transition (~ 10 km or less) that the LAB cannot be produced by thermal or compositional contrast alone, but must represent a transition from solid (melt-free) lithosphere to a porous asthenosphere containing at least a few percent of partial melt or fluid phase. Thus, the LAB

Lithosphere, Continental,

Fig. 3 A schematic 3-D rendering of LAB conversion points beneath six permanent seismic stations (*red triangles*) in northeastern USA (From Rychert et al. 2005. With permission). Inset map at top shows location of 3-D rendering. Topography is shown as shaded relief on the upper 3-D panel. The lower surface represents the base of the lithosphere, which ranges in depth from 90 km (*orange*) to 110 km (*pink*). Blue circles on the LAB discontinuity surface indicate the conversion points of the Ps phases. Black lines connect piercing points to the station at which the conversion is observed (Rychert et al. 2005)

could correspond to the solidus, or point of incipient melting, in the mantle beneath the continent, or it could mark the depth at which an impermeable barrier (the lithosphere) blocks the upward migration of fluids or partial melts from deeper in the mantle. In either case, the LAB in the Rychert et al. study represents a remarkably sharp rheological boundary, implying an abrupt transition from rigid lithosphere to ductile asthenosphere. Subsequent studies employing similar methodologies to those of Rychert et al., however, have proven difficult to interpret (e.g., Rychert and Shearer 2009), in that LAB depths so measured, particularly those beneath the stable continental interior, are incompatible either with tomographic images or with expected lithospheric thickness based on xenolith data or heat flow analysis (Pollack 1986; Romanowicz 2009). Thus, while the lithosphere–asthenosphere boundary beneath continents may be sharp and readily identified in some areas, notably tectonic regions or those of younger age, it would appear that beneath large parts of the stable continents the LAB may simply be too diffuse and/or heterogeneous to be identified as a single coherent discontinuity.

Summary and Conclusions

Lithosphere, as it is understood in plate tectonic phraseology, is a term that was developed almost entirely in the context of

oceanic plates. There, the discontinuity separating oceanic lithosphere from asthenosphere is widely recognized to be a rheological boundary between a strong melt-free plate and a weak, probably partially molten asthenosphere. In many important respects, we now know that this easily visualized oceanic model – universally displayed in textbooks both elementary and advanced – is a cartoonish oversimplification when applied to the continental lithosphere. Although there do appear to be regions where the continental lithosphere is almost as well defined as it is beneath ocean basins, the distinction between lithosphere and asthenosphere at depth beneath the continents, specifically the boundary between the two, is still shrouded in uncertainty. The failure of our ability seismologically to determine where lithosphere ends and asthenosphere begins has major implications for plate tectonic models in a dynamical earth. If we do not understand the coupling (or lack thereof) between lithosphere and asthenosphere, and the depth at which that occurs, then the task of sorting out the geodynamical drivers for plate tectonics becomes an exceedingly difficult exercise. While seismology ultimately has the ability to ferret out the truth of how continental plates are coupled or decoupled from the mobile mantle beneath, we are not quite at that point in the science. Nonetheless, the study of the continental lithosphere, particularly the lithospheric mantle, is entering a period of unprecedented expansion. In the USA, the EarthScope program's Transportable Array of 400 broadband seismic systems has

migrated to the country's midsection, with nearly 1,000 stations occupied at the time of this writing. Similar large-scale programs are well underway in Japan, China and Europe, giving hope that within the next several years the continental lithosphere and the lithosphere–asthenosphere boundary will have been mapped at high resolution over much of the globe's surface.

Definition

Thermal conduction is the dominant form of heat transport across the lithosphere. The thermal structure of the continental lithosphere and its thickness are determined by the distribution of heat-producing elements in the crust and lithospheric mantle and the boundary condition at its base. Vertical seismic velocity profiles, geothermobarometry on mantle xenoliths, and sedimentary records of subsidence provide additional constraints on lithospheric thickness and temperature. The base of the lithosphere can be defined as the intersection of the conductive temperature profile with the mantle isentrope.

Introduction

The lithosphere is the superficial shell or *boundary layer* that lies at the top of the convecting mantle and experiences little internal deformation. The concept of lithosphere has evolved

over the years, leading to various definitions and estimates of its thickness. The base of the lithosphere was initially defined by a seismic low-velocity zone associated with partial melting. In the oceans, it was also determined by the variations of seafloor depth and surface heat flux as a function of age. It was clear from the beginning that all these definitions are related to the thermal structure. For instance, partial melting requires temperatures above the solidus of mantle rocks. These definitions were introduced, and tested, in the oceans with varying degrees of success but could not be readily extended to the continents. Over large continental areas, no seismic low-velocity zone can be detected, and, for a long time, the meager scattershot heat flux data set allowed conflicting interpretations.

In the oceans, the lithosphere is made out of homogeneous starting material that is well characterized. It is affected by few thermal perturbations and tectonic events during its short residence time at Earth's surface. Its thermal structure and thickness are essentially functions of only one variable, age, and evolve in simple ways that can be studied with several independent geophysical techniques. In comparison, the continental lithosphere is heterogeneous and thick. Not only was it formed a long time ago by processes that are still debated today, but it has been affected by a succession of perturbations and tectonic events which have left their imprints. Its thermal structure is sensitive to the large amounts of heat-producing elements in the crust and cannot be characterized by age only.

Because the continental lithosphere is thick, its thermal relaxation time is very large, which offers opportunities to study mechanisms that are no longer active today. Because of its old age, it preserves structural and chemical records of ancient geological processes. From a purely thermal standpoint, it plays an important role in regulating the Earth's heat loss and in storing large quantities of radioactive elements that are no longer available to power mantle convection.

The Thermal Boundary Layer of Mantle Convection

The lithosphere can be defined from a purely thermal standpoint. There are two basic mechanisms of heat transport within the Earth, conduction and convection. Convection refers to the transport of energy by matter that is set in motion by buoyancy forces. Without mass transport, energy can be transferred by conduction in association with a temperature gradient. These mechanisms are important in different parts of the Earth. At shallow depths beneath the surface, the cold upper layer does not deform easily on geological timescales, so that conduction is the dominant heat transport mechanism. The lithosphere may be defined from this perspective, but this definition does not account for heat that is supplied by convection from below. One must add a relatively thin convective

boundary layer at the base of the lithosphere, which connects the rigid and purely conductive upper region to the well-mixed mantle below. In this basal boundary layer, heat transport by conduction is not negligible, as discussed below in more detail.

Thermal Structure

In the continental lithosphere, heat is in part supplied from below by convection and in part generated by the decay of radioactive elements. In steady state and assuming that heat transport occurs in the vertical direction only, the heat balance equation is:

$$0 = -\frac{dq}{dz} + H \quad (1)$$

where z is the depth, q is the vertical heat flux, and H is the rate of heat production. In the upper part of the thermal boundary layer, there is no convection, and the heat flux is given by the Fourier law of heat conduction:

$$q = -\lambda \frac{dT}{dz} \quad (2)$$

where T is temperature and λ thermal conductivity. The temperature gradient can be measured at Earth's surface in deep boreholes and determined in the lithospheric root below the crust using the thermodynamic equilibrium conditions between mineral assemblages found in the sample from the mantle, mantle xenoliths found in kimberlite pipes. Typical values in stable continents are 15 K km^{-1} and 5 K km^{-1} , respectively (Fig. 1). The difference between these two values is due to radiogenic heat production in the continental crust. Below the lithosphere, the temperature gradient is dictated by the convective regime and is expected to be close to an isentrope. By definition, entropy is conserved when going up or down an isentrope, such that:

$$\frac{dT_S}{dz} = \frac{\alpha g T_S}{C_p} \quad (3)$$

where α is coefficient of thermal expansion, g is acceleration of gravity, T_S is temperature, and C_p is specific heat at constant pressure. For the Earth's mantle, the isentropic gradient is typically 0.5 K km^{-1} , which is much less than the conductive gradient in the lithospheric mantle. One identifies the isentrope by its *potential temperature*, i.e., the value of its temperature at atmospheric pressure.

Three different depths may be defined in the thermal boundary layer (Fig. 2). The shallowest boundary, h_1 , corresponds to the base of the rigid upper part and of what we shall call the thermal lithosphere. The deepest boundary, at depth h_3 , corresponds to the top of the well-mixed mantle and lies

Lithosphere, Continental: Thermal Structure, Fig. 1 Pressure and temperature estimates from studies of mineral assemblages in xenoliths from the lithospheric mantle beneath the Kirkland Lake kimberlite pipe, Abitibi subprovince, Canadian Shield. Data are taken from Vicker (1997). The best fit (dashed line) indicates a temperature gradient of 5 K km^{-1} . Note that it intersects Earth's surface at a temperature of about 400 °C , showing that the temperature gradient is larger than 5 K km^{-1} in the crust

along the mantle isentrope. With no knowledge of boundary layer characteristics and heat transport mechanisms, one cannot determine h_1 . An intermediate depth, h_2 , is obtained by downward extrapolation of the conductive geotherm to the mantle isentrope. h_3 is obtained from seismic velocity anomalies, as it is such that temperatures do not deviate significantly from those beneath oceans or from the average mantle velocity profile. These thickness determinations say nothing about h_1 . Yet, it is h_1 which defines the mechanically coherent unit (the “plate”) which moves at Earth's surface and sets the thermal relaxation time which follows tectonic and magmatic perturbations. Uncertainty on this thickness has severe consequences because the diffusive relaxation time is $\propto h^2/\kappa$, where κ is thermal diffusivity.

In steady state, Q_0 , the heat flux at Earth's surface, is obtained by integrating the heat balance Eq. (1) and can be broken down in three components:

$$Q_0 = Q_{\text{crust}} + Q_{\text{lith}} + Q_b \quad (4)$$

where Q_{crust} and Q_{lith} stand for the contributions of heat sources in the crust and in the lithospheric mantle and Q_b is the heat flux at the base of the lithosphere. To describe heat transport mechanisms and the lithosphere structure, one must

Lithosphere, Continental: Thermal Structure, Fig. 2 Left: Schematic vertical temperature profile through the continental lithosphere, illustrating three different thicknesses and temperatures. Thickness h_1 corresponds to the rigid upper part of the thermal boundary layer. h_2 is determined by downward continuation of the temperature profile in the rigid upper part to the isentrope that approximates the temperature profile

in the well-mixed convective mantle. h_3 denotes the base of the thermal boundary layer, such that temperature is along the well-mixed isentrope. Right: three different regions with different heat transport characteristics. Heat is transported by conduction only above depth h_1 and by convection only below depth h_3 . Between these two depths, a convective boundary layer is such that both heat transport mechanisms are important

introduce three temperatures, T_0 at the upper boundary, which, for all practical purposes, may be taken as fixed and equal to 0 °C, T_b at the base of the lithosphere, and T_m along an isentrope in the well-mixed convective interior (Fig. 2). One can reasonably assume that the mantle potential temperature is the same beneath continents and oceans and hence that it can be deduced from the composition of mid-ocean ridge basalts (Kinzler and Grove 1992). Today, this temperature is about 1325 °C. T_b , the temperature at the base of the thermal lithosphere (the rigid lid), cannot be determined from geophysical measurements.

In the oceans, one may ignore Q_{crust} and Q_{lith} , and, for seafloor older than 100My, the surface heat flux is equal to the basal heat flux. In this case:

$$Q_0 = Q_b = \lambda \frac{T_b - T_0}{h_1} = \lambda \frac{T_m - T_0}{h_2} \quad (5)$$

Well-established convection theory leads to a closure equation relating Q_b to the temperature difference across the convective boundary layer, $(T_m - T_b)$ (Davaille and Jaupart 1993; Solomatov 1995). In this case, therefore, measurement of the surface heat flux Q_0 allows determination of the basal heat flux and of the temperature difference $(T_m - T_b)$. In turn, this leads to the values of thicknesses h_1 and h_2 as well as of basal temperature T_b . In the oceans, therefore, the values of all the variables can be deduced from surface measurements. In the continents, the problem is more complicated because the surface heat flux includes the crustal contribution Q_{crust} which may vary by large amounts. This crustal component is typically about 30 mW m⁻² out of a total of 42 mW m⁻² in Archean (i.e., older than 2.5Gy) cratons. In such conditions, surface heat flux measurements do not provide a direct measure of the heat flux at the base of the lithosphere, which must be inferred from other data with methods that will be discussed below. Q_{crust} depends on the composition of the continental crust, which itself reflects the past history of magma emplacement and tectonic deformation/accretion. Observations show that it varies by large amounts even in a single geological province. It cannot be calculated from first physical principles and must be determined on a case-by-case basis using a host of different measurements.

The lithosphere owes its physical properties to partial melting and melt extraction processes which leave a solid residue that is both less dense and mechanically stronger than the starting mantle material. Mechanical strength is due to both the lower temperature in the lithosphere than in the convective mantle and dehydration that occurred during partial melting (Pollack 1986). Melting may be achieved by two different mechanisms operating in different settings. One mechanism is decompression in an upwelling and has been

documented in considerable detail in mid-ocean ridges (McKenzie and Bickle 1988). Decompression melting begins at a depth which depends on mantle temperature and water content (e.g., 60–80 km for the oceans today). Continents are not linear features and were probably not generated by linear mantle upwellings such as present-day mid-ocean ridges. Their formation has been linked to large mantle plumes or subduction zones (Carlson et al. 2005). For mantle plumes, the mechanism is basically the same as that beneath mid-ocean ridges, and the depth where melting starts dictates the thickness of the buoyant solid residue. In a dry mantle, high potential temperatures are required for the generation of thick lithospheric roots (Herzberg 1983; Fig. 3). For a thickness of 250 km, for example, the mantle potential temperature must be about 1800 °C. On the other hand, if the Archean mantle was wet, melting occurred at shallower depths and at lower temperatures (Grove and Parman 2004). In this case, a second event is required to account for the large thickness of continental lithosphere, involving large-scale compression and/or thrusting. For both types of models, the lithosphere thickness provides a strong constraint on the mechanism of continent formation.

Heat Flux at the Base of the Continental Crust and at the Base of the Lithosphere

Constraints on the thermal structure of the continental lithosphere may be obtained with several geophysical methods. To obtain continuous temperature profiles, however, one can only use surface heat flux data and downward continue

Lithosphere, Continental: Thermal Structure, Fig. 3 Solidus temperature of dry mantle peridotite as a function of pressure and depth, from Herzberg (1983). Also shown are two isentropes that intersect the solidus at depths of 60 and 250 km

shallow temperature measurements. To this aim, one needs to specify the heat flux at the base of the lithosphere. A first step is to determine the amount of heat produced in the continental crust or, alternatively, the heat flux at the Moho discontinuity.

Uranium and thorium are the main heat-producing elements in rocks. They are located mostly in accessory minerals and grain boundaries, which depend weakly on the bulk chemical composition. Thus, their concentrations are not related to physical properties such as density and seismic velocity and cannot be retrieved from large-scale geophysical studies. In addition, they vary by large amounts at all scales, from that of a petrological thin section to that of a whole massif. Within an apparently homogeneous pluton, they can change in both vertical and horizontal directions due to fluid migration and late-stage alteration. In the Bohus granite, Sweden, for example, thorium concentrations vary by a factor of 5 over horizontal distances as small as a few tens of meters (Landstrom et al. 1980).

In a geological province, radio-element concentrations cannot be estimated using data from other provinces and must be measured in all the major rock types present. They depend on lithology and are high in granites and meta-sediments, so that a geological map gives a rough idea of the spatial distribution of heat production. With the very wide ranges that exist for each rock type, however, the standard deviation of the heat production distribution is large and often larger than the mean. As a consequence, a single thermal model for a province would gloss over the important lateral temperature variations that occur due to the heterogeneous crustal structure. For a reliable thermal calculation in a specific area, one cannot use the local heat production values of a few rock types found on the outcrop because temperatures are sensitive to heat that is generated over rather large volumes. Average heat production values must be determined on a scale that is intermediate between the dimensions of individual plutons and the size of the province.

Vertical variations of heat production can be determined in deep boreholes or from exposed crustal sections. On a vertical scale of ~ 10 km, data from the deep boreholes at Kola, in the Russian part of the Baltic Shield (Kremenensky et al. 1989), and the KTB, Germany (Clauser et al. 1987), show no systematic change with depth. At KTB, heat production between 8 and 9 km depth is the same as between 1 and 2 km and higher than above 1 km. At Kola, heat generation in the Archean rocks between 8 and 12 km is higher ($1.47 \mu\text{W m}^{-3}$) than in the shallower Proterozoic section ($0.4 \mu\text{W m}^{-3}$).

Over a crustal thickness scale, heat production is lower in mid-crustal assemblages than in the upper crust. This vertical variation is not monotonous and cannot be described by a simple function valid everywhere, as shown by exposed crustal sections such as the Vredefort in South Africa (Nicolaysen et al. 1981), the Cordilleran core complexes of

Lithosphere, Continental: Thermal Structure, Table 1 Element concentration and heat production in the continental crust. (From Rudnick and Gao (2014)). Element concentrations are given in ppm

	U	Th	K	$\mu\text{W m}^{-3}$
Upper crust	2.7	10.5	23,300	1.65
Middle crust	1.3	6.5	19,200	1.00

Arizona (Ketcham 1996), or the Pikwitonei-Sachigo and Kapuskasing-Wawa areas of Canada (Fountain et al. 1987; Ashwal et al. 1987). One robust feature is the depletion of lower crustal assemblages in comparison to upper and middle crustal ones (Table 1).

Table 1 lists estimates derived from global geochemical models of the crust and a very large number of measurements. The crust is split into three different crustal horizons corresponding to average regional seismic models. The model crust is 40 km thick with middle crust in the 12–23 km depth range and is such that $Q_{\text{crust}} = 36 \text{ mW m}^{-2}$. Another method relies on heat flux data and will be explained below (Table 2). With this method, one may also evaluate heat production variations between provinces. The two independent methods lead to comparable results and show that crustal heat generation typically accounts for more than half of the surface heat flux.

Heat Flux and Heat Production

With the large variations in the concentrations of heat-producing elements that have been documented in crustal rocks, it is not surprising that, in continents, the surface heat flux changes by large amounts over small horizontal distances of a few tens of kilometers. The largest anomalies occur in association with enriched granitic plutons. These plutons are usually of small size, and the local value of the heat flux is not representative of the average crust that lies below the measurement site. In such conditions, studies of the thermal structure of continents require large data sets. The challenge is to obtain average values of heat flux and heat production that are representative of the whole crust in

an area. We discuss the scales over which this can be done in a reliable manner.

There is only a weak relationship between local values of heat flux and heat production in a geological province (Fig. 4). For a representative thermal model, one must determine an average heat flux value over an area that is sufficiently large for the smoothing of small-scale variations due to isolated anomalous massifs. Figure 4 also shows data for ten $\approx 250 \text{ km} \times 250 \text{ km}$ windows distributed in North America. These are located in the same area as the individual heat flux values discussed previously and show that a relationship between heat flux and heat production begins to emerge at this scale. Even at this scale, the relationship is not defined tightly due to insufficient sampling of heat production. A single heat flux value is sensitive to crustal heat production over large horizontal distances and records the contribution of many different geological units. In contrast, the heat production values correspond to a small number of rocks found at shallow depth in boreholes used for heat flux determinations. The limited sampling achieved at a scale of 250 km does not account for the full range of rock types and heat production rates in the crust. For representative heat production averages, one needs to work at a larger scale. Figure 4 shows data for five major geological provinces in North America with typical dimensions of $\approx 500 \text{ km} \times 500 \text{ km}$. These provinces cover the geological history of the stable continent and represent different types of continental crust. Furthermore, they have been extensively deformed and eroded, so that rocks from a large range of depths can be found at the surface. The metasedimentary-plutonic belts of the western Superior Province, Canadian Shield, for example, include rocks from all metamorphic grades up to granulite facies. The province-wide averages exhibit a remarkable linear relationship, with a heat flux intercept of $\sim 33 \text{ mW m}^{-2}$ corresponding to crust with zero surface heat production. The data for the ten $\approx 250 \text{ km} \times 250 \text{ km}$ windows lie close to this global linear relationship (Fig. 4).

The Moho heat flux is equal to:

$$Q_M = Q_0 - Q_{\text{crust}} = Q_{\text{lith}} + Q_b \quad (6)$$

which depends on heat production in the lithospheric mantle and on the heat flux at the base of the lithosphere. Both components come from depths larger than the crustal thickness, so that lateral variations, if they exist, get smoothed out by horizontal diffusion. For an average lithospheric thickness of 250 km, variations of the basal heat flux Q_b over wavelengths smaller than 500 km are not detectable in the surface heat flux (Mareschal and Jaupart 2004). A similar statement can be made for the contribution of heat sources in the lithospheric mantle, Q_{lith} . Thus, on scales that are smaller than 500 km, one must consider that the Moho heat flux is

Lithosphere, Continental: Thermal Structure, Fig. 4 Relationship between heat flux and radiogenic heat production in North America at different scales, from Levy et al. (2010). Top panel: for individual measurements, there is clearly no relationship between the two. Middle panel: at an intermediate scale of about 200 km, a relationship between the average values of heat flux and heat production begins to emerge. The dashed line corresponds to the best-fit linear relationship defined by province-wide averages. Bottom panel: it shows a strong correlation between the average values of heat flux and heat production for the five major geological provinces of North America. The best-fit linear relationship has a slope of 9 km and an intercept of 33 mW m^{-2} . Symbols are as follows: App, Appalachian Province (400My); Gre, Grenville Province (1100My); THO, Trans-Hudson Orogen (1800My); Sup, Superior Province (>2500My); Slave, Slave Province (>2500My)

uniform and that variations of the surface heat flux come solely from changes of crustal heat production.

The strong correlation that is observed between the province-wide average surface heat flux and heat production indicates that variations of the Moho heat flux are small throughout the whole North American continent (Fig. 4). If there were large variations of the Moho heat flux, they would need to be compensated by opposite variations of the average lower crustal heat production. No physical mechanism can explain how such independent variables can be linked to one another. Variations of the Moho heat flux are therefore less than the intrinsic uncertainty on the heat flux measurements and the magnitude of departures from the heat flux-heat production relationship, which is about $2\text{--}3 \text{ mW m}^{-2}$ (Mareschal and Jaupart 2004). The absolute value of the Moho heat flux is not specified by this analysis, however, and this issue is discussed in the next section.

The Moho Heat Flux

Direct determination of the heat flux through the lithospheric mantle can be made using xenolith samples brought from lithospheric depths by powerful *kimberlitic* eruptions. Coexisting mineral assemblages and mineral compositions allow estimates of pressure and temperature and of the geothermal gradient. Together with a thermal conductivity estimate, they lead to values of the heat flux beneath the crust. For the Kirkland Lake pipe, within the Superior Province, Canada (Fig. 1), Rudnick and Nyblade (1999) obtained a best-fit

Moho heat flux estimate of $\approx 18 \text{ mW m}^{-2}$ within a total range of $17\text{--}25 \text{ mW m}^{-2}$. Russell and Kopylova (1999) derived a best fitting value of 15 mW m^{-2} , within a range between 12 and 24 mW m^{-2} , for the Jericho kimberlite area of the Archean Slave Province, also in Canada. Figure 5 shows data from several kimberlite pipes in the Slave Craton (2008). There are significant temperature differences between the different data sets. Surprisingly, the youngest eruptions, which provide recent samples of the lithospheric mantle, yield the highest temperatures. A similar result is obtained in the Kaapvaal Craton, South Africa (Michaut et al. 2007). If these temperature variations are indeed due to age and reflect the time evolution of lithospheric temperatures, they are not consistent with secular cooling of the Earth's mantle. The pipes do not overlap so that the data may in fact record lateral variations of temperature in the lithospheric mantle, which can only be explained by changes of heat production. Nevertheless, these data lead to similar values of the temperature gradient and heat flux.

Bounds on the Moho heat flux can be obtained by taking advantage of the variations of heat flux and crustal structure in a geological province. Combined with heat production data for the various rock types involved, one can isolate the variable crustal component and the uniform Moho heat flux. In Canada, Moho heat flux values of $10\text{--}15 \text{ mW m}^{-2}$ have thus been derived for the Grenville Province, the Trans-Hudson Orogen (THO), for the Abitibi belt of the Superior Province (Jaupart and Mareschal 2015). Crustal thickness and

Lithosphere, Continental: Thermal Structure, Fig. 5 Relationship between temperature and depth in the lithospheric mantle of the Slave Province, Canada, from Canil (2008). The Slave Province is small and has been pierced repeatedly by kimberlite pipes in the same area. Left panel: data from the two oldest pipes. Right panel: data for two young

pipes compared to those for the oldest pipe in the area. On average, temperature estimates from the two young pipes are larger than those of the older pipes by about 150 K . Such differences may indicate lateral temperature variations in the lithospheric mantle

composition can also be constrained by combining seismic refraction, gravity, and heat flux. Such methods lead to values of Q_M between 7 and 15 mW m⁻².

Another method relies on P_n velocities from seismic refraction surveys (Perry et al. 2006). For given values of the surface heat flux, the Moho temperature depends on the amount of crustal heat production and hence on the Moho heat flux. One can therefore obtain a relationship between Moho temperature and seismic velocity with the Moho heat flux as control parameter. One can also derive independently a relationship between temperature and seismic velocity using laboratory measurements of elastic properties and seismic velocities, with the bulk mantle composition as control parameter. The two relationships are only consistent with one another over a restricted range of composition and Moho heat flux. For depleted mantle compositions appropriate to the Superior Province, a good fit between predicted and observed P_n velocity values is obtained if the Moho heat flux is within a range of 12–25 mW m⁻² (Perry et al. 2006).

The three different and independent methods that we have described have all been applied to the Abitibi belt in the Canadian Shield and can be combined to tighten the final range to 12–15 mW m⁻² for that subprovince. Lower and upper bounds on the Moho heat flux have been derived using other arguments. Upper bounds on the mantle heat flux are obviously provided by the lowest heat flux measured. Values of 20–23 mW m⁻² have been reported within the Canadian Shield (Mareschal et al. 2000). Regional values as low as 18 mW m⁻² have also been reported for the Baltic or Siberian Shield. One can refine this estimate to 18 mW m⁻² using lower bounds on crustal heat production.

The methods that we have described here rely on different data and hence are associated with different sources of uncertainty. That such completely independent methods converge to similar results allows some confidence in the final range obtained. Values lower than 12 mW m⁻² are not consistent with the xenolith data, whereas values higher than 18 mW m⁻² can be excluded because of the heat flux data. This upper bound appears to be valid for all the shields (Jaupart and Mareschal 2015).

Lithospheric Geotherms

Using information on heat flux values at the surface and at the Moho, one may determine geotherms through the lithosphere. The calculation requires values for thermal conductivity that are discussed in the Appendix. Fig. 6 shows two such geotherms for two provinces in North America, which are consistent with both seismic and heat flux data (Levy et al. 2010). These two geotherms intersect the well-mixed mantle isentrope at different depths, indicating large lateral thickness variations for the continental lithosphere. The maximum thickness is reached beneath the Archean Superior Province and is estimated to be 280 ± 30 km.

Lithosphere, Continental: Thermal Structure, Fig. 6 Two steady-state lithospheric geotherms beneath the Appalachian and Superior provinces of North America, from Levy et al. (2010). These two geotherms were deduced from measurements of the surface heat flux and heat production and were constrained by requiring consistency with seismic data. The dashed line is the isentrope for a potential temperature of 1350 °C

Thermal Transients

Because the continental lithosphere is thick, it is characterized by a long thermal relaxation time. For a thickness of 250 km and a thermal diffusivity κ equal to 10^{-6} m² s⁻¹, the characteristic diffusion time $\tau = h^2/\kappa$ is ≈ 2 Gy. This is much longer than that of the oceanic lithosphere, which is only about 200 My (for a thickness of 80 km). We shall now discuss two types of thermal transients in thick lithosphere.

Thermal relaxation of the lithosphere following a deep thermal perturbation can lead to subsidence, which has been recorded in intracratonic sedimentary basins located away from active plate boundaries. Subsidence histories for two such basins of North America, the Michigan and Williston basins, are shown in Fig. 7 and emphasize their long durations exceeding 200 My. On the basis of models for heat transport and cooling in the vertical direction only, the thickness of the North American lithosphere is found to about 115 km beneath the Michigan basin and 270 km beneath the Williston (Haxby et al. 1976; Ahern and Mrkvicka 1984). There is no obvious explanation for such a large thickness difference in the middle of the North American continent, which suggests that the subsidence models may be oversimplified. These models

Lithosphere, Continental: Thermal Structure, Fig. 7 Subsidence histories for the Michigan and Williston basins, North America

rely on 1-D calculations and hence are only valid if the thermal anomaly stretches over a horizontal distance that is much larger than the lithosphere thickness. The Michigan and Williston basins have been attributed in large part to plate flexure driven by a deep load (Nunn and Sleep 1984; Ahern and Mrkvicka 1984). This load is related to the initial thermal anomaly and has a radius of about 120 km beneath the Michigan basin (Haxby et al. 1976), which is smaller than the thickness of the lithosphere beneath the North American craton. In these conditions, the assumption of purely vertical heat transfer is not tenable.

Kaminski and Jaupart (2000) have reevaluated thermal models for the continents by taking into account lateral heat transport within thick lithosphere. They considered a lithosphere of thickness h with a cylindrical thermal anomaly of radius a between depths h and b . At the surface ($z = 0$), temperature is fixed at T_o . At steady state, the base of the lithosphere is at $T = T_o + \Delta T$. Assuming, for example, that the thermally perturbed region is initially at a uniform temperature $T_o + \Delta T$, temperature can be written as the sum of the equilibrium temperature and a dimensionless perturbation θ :

$$T(r, z, t) = T_o + \Delta T \left[\frac{z}{h} + \theta(r, z, t) \right], \quad (7)$$

where r is the radial distance. The temperature perturbation may be expressed in terms of a vertical component θ_z , which corresponds to the 1-D solution, and a radial component which can be calculated using Bessel functions. For thermal anomalies with planforms that are not circular, lateral heat transfer is dominated by the smallest horizontal dimension.

The acceleration of cooling due to lateral heat loss can be measured simply by the time to achieve 90% of the final subsidence, noted τ_2 , scaled to that for an infinitely wide initial perturbation, τ_1 (corresponding to the 1-D calculation) (Fig. 8). Results are sensitive to the boundary condition at the base of the lithosphere and show that the impact of lateral heat

Lithosphere, Continental: Thermal Structure, Fig. 8 Time to achieve 90% subsidence in thick lithosphere as a function of the radius of the deep lithospheric thermal anomaly, a (scaled to the lithosphere thickness h). The subsidence time has been scaled to the value obtained with a 1-D thermal model for purely vertical heat transport. Results have been obtained for two different boundary conditions at the base of the lithosphere. (Adapted from Kaminski and Jaupart (2000))

transport is significant for $a/h < 1$, corresponding to $a < \approx 250$ km in the North American craton. This is the case of all the major intracratonic basins. In comparison to the oceans, thermal relaxation in the continents is lengthened by the larger lithosphere thickness and shortened by lateral heat transport. Different subsidence histories and durations are generated by the same basic process operating over different lateral distances.

Secular Transients

We have shown above that continental temperatures depend strongly on radiogenic heat production. Thus, continents cool down continuously due to the rundown of radioactivity with time. One should also add that conditions at the base of the lithosphere also evolve with time due to secular cooling of the whole Earth. This is ill-constrained and we focus our attention to the effects of decaying heat sources. For the Appalachian geotherm of Fig. 6, for example, crustal heat production contributes about 300 °C. For average Th/U and K/U ratios, radiogenic heat production decreases by a factor of 2 in about 2.7 Gy. We thus deduce that continental temperatures decrease at a rate of about 50 K Gy⁻¹, which is comparable to the bulk mantle cooling rate (Abbott et al. 1994). This simple argument relies on a quasi-steady-state approximation, such that ancient geotherms are calculated using the steady-state heat equation together with past values of heat production. For thick lithosphere, this approximation is not valid and may lead to significant errors.

In thick continental lithosphere, the timescale for diffusive heat transport is comparable to the half-lives of uranium, thorium, and potassium. As noted above, the characteristic time for heat diffusion equal to h^2/κ is 2 Gy for 250-km-thick

Lithosphere, Continental: Thermal Structure, Fig. 9 Present-day vertical temperature profile for transient thermal model with decaying heat sources (thick line) compared with two steady-state geotherms (solid line for present-day heat production; dashed line, for heat production rate values 1.5 Gy ago) for the same set of parameters ($h = 250$ km, crustal heat production $A_c = 1.0 \mu\text{W m}^{-3}$, lithospheric mantle heat production $A_m = 0.02 \mu\text{W m}^{-3}$, basal heat flux $Q_b = 10 \text{ mW m}^{-2}$). Surface heat flow is of 49 mW m^{-2} for the transient solution, 46 mW m^{-2} for the present-day steady-state profile, 62 mW m^{-2} for the 1.5 Ga steady-state profile

lithosphere, which is close to the decay time of radiogenic heat production (≈ 2.7 Gy). Thus, heat diffusion is not efficient enough to keep up with the decaying heat sources, and lithospheric temperatures are not in equilibrium with the instantaneous rate of heat production. In these conditions, the vertical temperature profile exhibits significant curvature and may be hotter than a steady-state profile by as much as 150 K depending on the absolute value of the heat generation rate (Fig. 9). Another consequence is that forcing a steady-state temperature profile through xenolith (P-T) data leads to an overestimate of the mantle heat flux.

For illustration purposes, Fig. 9 shows the instantaneous vertical temperature profile with decaying sources and a steady-state geotherm derived for the same present-day values of crust and mantle heat production. The difference between the two geotherms increases with depth because of increasingly inefficient transport of heat to the Earth's surface. For comparison, we have also calculated a steady-state geotherm corresponding to heat production values 1.5 Gy ago. The transient geotherm falls between the steady-state geotherms calculated for heat production rates at 0 and 1.5 Ga, showing that it is sensitive to heat generation in the past. At the base of the lithosphere, all geotherms are parallel because of the constant heat flux bottom boundary condition. Secular transient behavior is not important at shallow depths,

Lithosphere, Continental: Thermal Structure, Fig. 10 Xenolith P-T data from the Kimberley, Jagersfontein, Premier and Frank Smith kimberlite pipes, Kaapvaal Craton, South Africa (Rudnick, personal communication, 2003). Thick line: vertical temperature profile for a transient thermal model with decaying heat sources and for a lithosphere thickness of 225 km. Parameter values are crustal heat production $A_c = 0.8 \mu\text{W m}^{-3}$, mantle heat production $A_m = 0.025 \mu\text{W m}^{-3}$, and basal heat flux $Q_b = 12 \text{ mW m}^{-2}$. Note that the geotherm terminates above several deep data points, due to the starting assumption on lithosphere thickness

due to the efficiency of diffusive heat transport over small distances. In the crust, differences between the transient and present-day steady-state profiles are very small and can be neglected for all practical purposes. Between 50 and 150 km depth, heat flux is about 13 mW m^{-2} for the present-day steady-state model and 16 mW m^{-2} for the transient one. Maximum departure from thermal equilibrium is achieved at the base of the lithosphere. The magnitude of transient effects essentially depends on mantle heat production as well as on lithosphere thickness. Large values of heat production in the lithosphere do not introduce large transients at shallow depths. In contrast, even small values of heat production lead to significant effects in a thick lithosphere.

The secular transient geotherm is compared to xenolith (P-T) data from Kaapvaal Craton, South Africa, for $h = 225$ km in Fig. 10. For this solution, the surface heat flux is 47 mW m^{-2} , which is close to measurements in this region, and heat production in the lithospheric mantle is $0.025 \mu\text{W m}^{-3}$, which lies in the lower range of values proposed by Rudnick and Nyblade (1999). The basal heat flux is 12 mW m^{-2} . The Kaapvaal xenolith (P-T) data suggest a change of slope in the geotherm at a pressure of about 5 GPa (Bell et al. 2003). According to some authors, this marks the transition between lithosphere and asthenosphere, with the deepest data points belonging to the convecting mantle below

the lithosphere. Rudnick and Nyblade (1999) and Bell et al. (2003) have argued that all data points belong to unperturbed lithosphere. Significant curvature of the secular transient geotherm allows a good fit to all the data and does not suggest a break in the geotherm.

Due to the intrinsic decay of radioactive heat sources, the lithospheric mantle therefore undergoes secular cooling even when thermal conditions at the base of the lithosphere remain steady. Predicted cooling rates are in the range of 50–150 K Gy⁻¹. Such transient behavior also has implications for heat flow studies. Assuming that the decay of radiogenic heat production can be represented by a single exponential, such that $A_m(t) = A_o h \exp(-\alpha t)$, the contribution of lithospheric heat production to the surface heat flux is:

$$\Delta Q_{\text{lith}}(t) = A_o h \frac{\tan \sqrt{\alpha \tau}}{\sqrt{\alpha \tau}} \exp(-\alpha t) \quad (8)$$

This is compared to the instantaneous amount of heat produced in the lithosphere:

$$\Delta Q_{\text{lith},i}(t) = A_o h \exp(-\alpha t) \quad (9)$$

Ratio $Q_{\text{lith}}/Q_{\text{lith},i}$ increases as a function of lithosphere thickness and is 1.5 for $h = 300$ km, for example. This shows that surface heat flux measurements record some time-average of the deep lithospheric heat production.

Summary

The continental lithosphere is much thicker than its oceanic counterpart, and its thermal structure depends strongly on radiogenic heat production in both the crust and in the mantle. Because of these two characteristics, its behavior depends on its geological history and is not a simple function of age. Beneath Archean shields, it can be as thick as 300 km.

Appendix: Thermal Conductivity

For an isotropic medium, Fourier's law is:

$$\mathbf{q} = -\lambda \nabla T \quad (10)$$

where λ is the thermal conductivity measured in W m⁻¹ K⁻¹. More generally, if the medium is not isotropic, the thermal conductivity must be defined as a second-order tensor. Thermal conductivity can be broken into lattice and radiative components, which have different behaviors as temperature and pressure change.

At low temperatures, heat transport is in large part affected by lattice vibrations. Lattice conductivity decreases with increasing temperature.

At larger temperatures, electromagnetic waves transport energy in continuous media. Radiation is rapidly attenuated but the medium re-emits energy if the temperature is sufficiently high. In a temperature gradient, the net energy flux will be $\propto T^3 \nabla T$, which has the same form as the flux for lattice conduction. One can therefore define a radiative component of conductivity, λ_R , such that the radiative heat flux is:

$$\mathbf{q}_R = -\lambda_R \nabla T \quad (11)$$

The gray body law states that:

$$\lambda_R = \frac{16}{3} \frac{n^2}{\epsilon} \sigma T^3 \quad (12)$$

where n is the refractive index, ϵ is the opacity, and σ is the Stefan constant of blackbody radiation ($\sigma = 5.67 \times 10^{-8}$ W m⁻² K⁻⁴).

Lattice Conductivity

For individual crystals, theoretical arguments suggest that, below the Debye temperature, the temperature dependence of lattice conductivity takes the following form:

$$\lambda(T) = \lambda_{298} \sqrt{\frac{298}{T}} \quad (13)$$

For polycrystalline assemblages, this equation is no longer valid and one relies on empirical fits to the data. Reasonable agreement can be obtained with a relationship of the type:

$$\lambda(T) = A + \frac{B}{350 + T} \quad (14)$$

where T is in °C and where constants A and B depend on the rock type (Table 3).
